Portneuf River Subbasin at a Glance

<i>Hydrologic Unit Code</i>	17040208
<i>Number of 303(d) Listed Reaches</i>	27
<i>Beneficial Uses Affected</i>	Cold Water Biota, Salmonid Spawning, Primary and Secondary Contact Recreation
<i>Listed Pollutants of Concern</i>	Sediment, Nutrients, Bacteria, Flow Alteration, Oil and Grease, Dissolved Oxygen
<i>Major Land Uses</i>	Agriculture, Rangeland, Urban
<i>Subbasin Area</i>	1,360 square miles

I. EXECUTIVE SUMMARY

The Portneuf River subbasin drains about 1,360 square miles in southeast Idaho. The subbasin has numerous documented water quality problems which affect support of beneficial uses in water bodies listed as water quality limited. The following pollutants are found on the 1994 and 1996 303(d) list for the streams in the Portneuf River subbasin: sediment, nutrients, bacteria, flow alteration, oil and grease, and dissolved oxygen. There are 27 water quality limited segments in the subbasin which include the mainstem river, 16 tributaries, and one reservoir. All stream segments on the 303(d) list include sediment as a pollutant of concern and roughly half are listed for nutrients. The [REDACTED] Portneuf River also includes on its list bacteria, flow alteration, and oil and grease. Hawkins Reservoir is the only waterbody listed for dissolved oxygen.

In addition to those pollutants already identified on the 303(d) list, several other problems exist in the Portneuf River. Exceedances of state water quality standards for temperature have been documented. Information from several reports suggest that metals are at higher levels than found naturally, especially in sediments of the lower Portneuf River. The effect of these higher concentrations of metals on beneficial uses has not been determined. Anecdotal evidence indicates that low levels of dissolved oxygen may be occurring in areas other than Hawkins Reservoir. Recent sampling by the U. S. Geological Survey showed high levels of polychlorinated biphenyls (PCBs) in both fish flesh and stream sediments.

Several sources of pollutants have been identified. Agriculture has been implicated in flow alteration and contributing sediment and nutrients into the Portneuf River. Sediment can also originate from streambanks, streambeds, and natural causes. Bacteria can result from livestock, wildlife, or human sources. Urban/suburban inputs influence sediment, nutrients, bacteria, and oil and grease. Stormwater runoff typically carries sediment, nutrients, bacteria, and oil and grease. Two NPDES-permitted discharges add nutrients to the lower Portneuf River.

Some efforts, particularly within the agricultural community, have been undertaken to decrease pollutant inputs and thus improve water quality primarily in the upper Portneuf River. Both federal and state supported agricultural programs have resulted in decreases in sediment,

nutrients, and bacteria into the Portneuf River. The most successful program in terms of water quality improvement has been the Conservation Reserve Program.

Information from the Idaho Department of Environmental Quality's Beneficial Use Reconnaissance Project indicate that several streams on the 303(d) list are supporting their beneficial uses. These streams include: Gibson Jack, Mink, Walker, Bell Marsh, Goodenough, upper Garden, Dempsey, Pebble, and Toponce creeks.

Load analyses were done for bacteria, oil and grease, sediment, and nutrients. No load analysis was done for flow alteration. Data were considered insufficient to develop a load analysis for dissolved oxygen in Hawkins Reservoir although a target concentration 0.025 mg/l of total phosphorus is recommended. This target is based on the EPA "Gold Book" which recommends that total phosphates as phosphorus in lakes or reservoirs not exceed 0.025 mg/l to prevent the development of biological nuisances and to control accelerated or cultural eutrophication. Loads were allocated where sources were known and data sufficient for analyses.

Load reductions are presented in Table ES. Fecal coliform load reductions are based solely on a percentage reduction. Percent load reductions of fecal input into the mainstem Portneuf River ranged from 17% in the upper river to over an 80% reduction in the lower river.

An oil and grease load analysis was done only for stormwater runoff from the Pocatello-Chubbuck area. Although the target load capacity for oil and grease into the Portneuf River is greater than the estimated present input of 38 tons from stormwater runoff, the analysis indicates that under certain circumstances (e.g., short, intense thunderstorm after a period of dry weather) the target concentration could be exceeded. Thus, it is recommended that stormwater runoff not exceed its present estimated annual load.

The highest reduction of suspended sediment is needed in the lower Portneuf River and Marsh Creek. Estimated reductions at the USGS surface-water stations at Pocatello and Marsh Creek are about 66%. The percent reduction estimated for Topaz is 53%. The reductions by source based on land use are presented in the main text.

Highest levels of nutrients were observed in the lower Portneuf River below Pocatello. The overall reductions recommended at the Tyhee USGS surface-water station site are 86% for total inorganic nitrogen and 81% for total phosphorus. The greatest source of nutrients in the lower river are the springs followed by the Pocatello Sewage Treatment Plant (PSTP). The highest percent reductions occur at the PSTP at over 95% for both total inorganic nitrogen and total phosphorus. Reductions at the Pocatello gage site are 66% and 39% for total inorganic nitrogen and total phosphorus, respectively. Percent reductions of total inorganic nitrogen and total phosphorus at the Marsh Creek and Topaz gage sites ranged from 50-66% for total inorganic nitrogen and 15-33% for total phosphorus.

Data gaps abound for practically all Portneuf River pollutants. Information is needed on effects of pollutants on beneficial uses; links between reductions in pollutant input and support beneficial uses; long term sampling from throughout the year covering various hydrographic

Table ES. Load analyses of pollutants identified in the Portneuf River subbasin.

Site/stream reach	Estimated annual load	Mean	Target load or wasteload	Load reduction*	Percent reduction*
Fecal coliform (colonies/100 ml)**

regimes; and identification of sources of pollutants by tributaries and other discharges (e.g., canals, NPDES permitted dischargers, springs). The loading analyses relied heavily on data collected at the USGS gaging stations which is why these sites were chosen to monitor effectiveness of efforts to reach the target load capacities.

2. PORTNEUF RIVER SUBBASIN DESCRIPTION

2.1 General

The Portneuf River is a major subbasin in southeast Idaho (Figure 1). This fifth order river is approximately 100 miles long and drains an area roughly 1,360 square miles primarily in Bannock and Caribou counties but also in Bingham, Power, and Oneida counties (Figure 2). Marsh Creek is the only "major" tributary to the Portneuf River. Other creeks in the subbasin include Mink, Rapid, Garden, Hawkins, Birch, Dempsey, Pebble, Twentyfourmile, and Toponce creeks. Chesterfield Reservoir is the largest reservoir in the subbasin at 1,245 acres.

The Portneuf River lies entirely within the Northern Basin and Range Ecoregion at the northeastern extreme of the Basin and Range Physiographic province. The Northern Basin and Range Ecoregion is characterized by plains with low to high, open mountains. For the ecoregion as a whole, potential natural vegetation includes Great Basin sagebrush (*Artemesia* spp.), saltbush (*Atriplex* spp.), and greasewood (*Sarcobatus vermiculatus*). Land use of the desert and shrubland is grazing. Soils are aridisols.

The geology of the subbasin is mostly sedimentary with some basalt in the Bancroft area, along the lower reach of Marsh Creek around Inkom, and along the Portneuf River mainstem from Inkom to Pocatello (Merrell and Onstott 1965). Underlying much of the subbasin are huge deposits of gravel, a result of the "break out" of Lake Bonneville into the Snake River basin through the Marsh Creek Valley (U.S. Army Corps of Engineers 1955). Major mountain ranges within the subbasin include: Bannock Range to the west, Portneuf Range in the middle and to the south, Fish Creek Range to the south, and Chesterfield Range to the east.

Topsoils are predominantly loess and very erodible (Merrell and Onstott 1965). In the lower Portneuf River subbasin, from Lava Hot Springs downstream, the texture, structure, and slope of the predominant silt loam soils generally make them highly erosive (Figures 3, 4; McNabb 1987). McNabb (1987) cited a 1986 Soil Conservation Service (now the Natural Resources Conservation Service) Highly Erodible Lands analysis which showed that 15.5% of the area soils usable for annual crops and alfalfa are highly erodible; 57.8% are potentially highly erodible; and 26.0% are not highly erodible.

Presently there are no threatened or endangered aquatic species in the Portneuf River subbasin. The Yellowstone cutthroat trout (*Oncorhynchus clarki bouvieri*) is listed as a sensitive species by the Bureau of Land Management and an imperiled subspecies by Idaho Department of Fish and Game (Idaho Department of Fish and Game, internet communication). Further, the U. S. Fish and Wildlife Service has recently been petitioned to list the Yellowstone cutthroat trout as

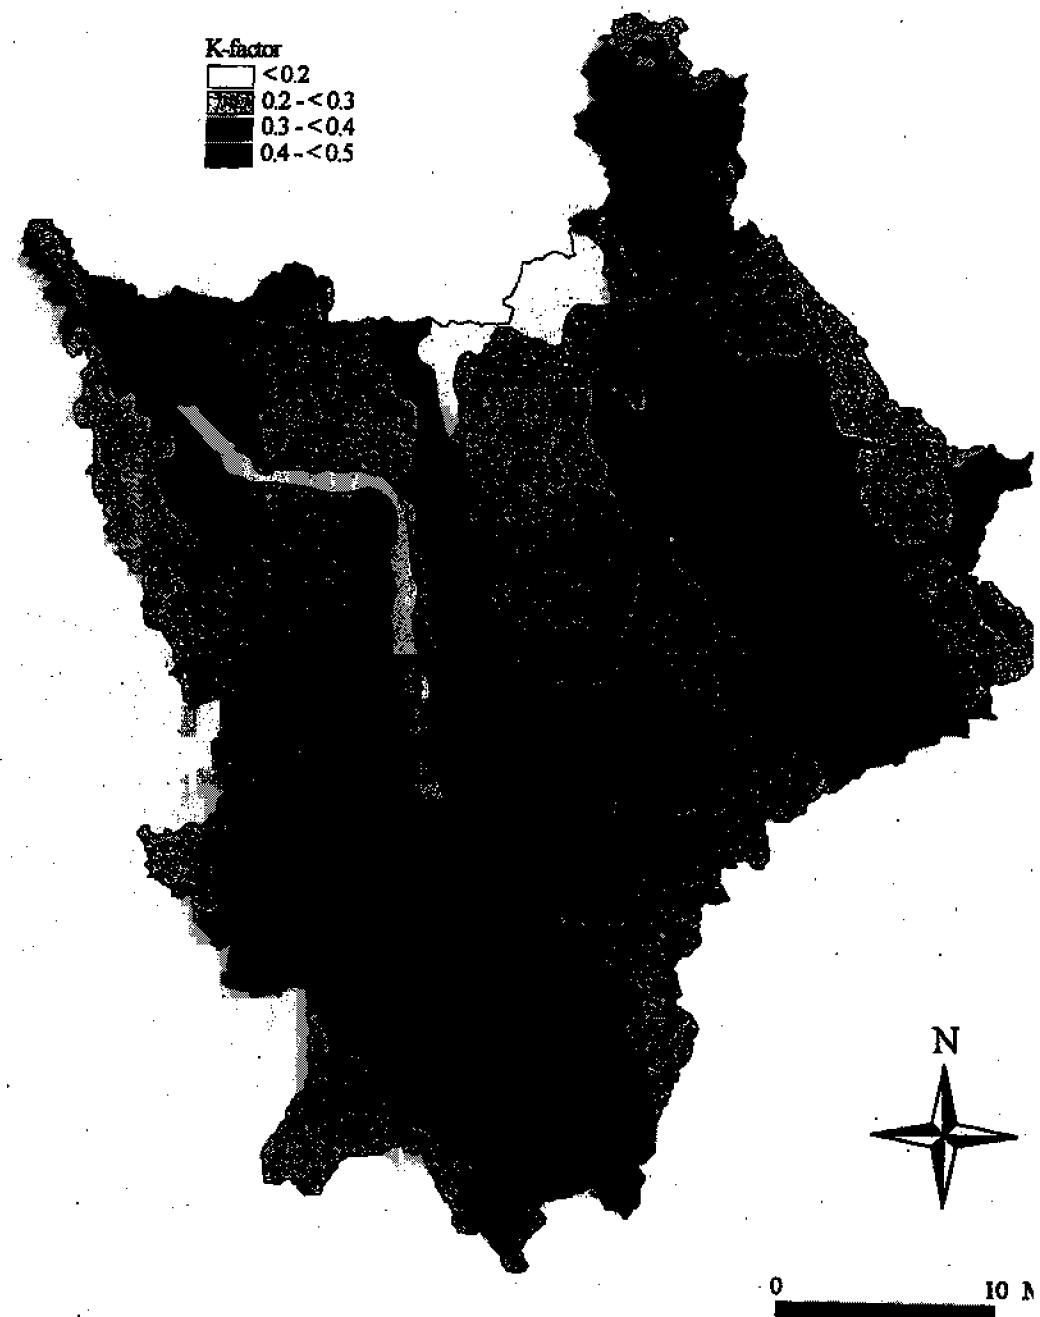

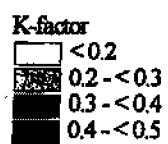

Figure 4. Weighted average K-factor (soil erosion capability) in the Portneuf River subbasin.
Soil erosion capability increases as the K-factor increases.

Scale 1:500000

a potentially threatened or endangered species; the decision is pending. Also on both lists (sensitive and imperiled), and possibly found in the Portneuf River subbasin, is the leatherside chub (*Gila copei*).

Elevations within the subbasin range from 9,280 ft to 4,350 ft. The average elevation is about 5,800 ft msl. Slopes on agricultural land vary from 0 to 20+ percent while rangeland slopes vary from 10 to 60 percent (Caribou Soil Conservation District 1991). Gradient in the mainstem of the Portneuf River changes from 23 feet/mile in the reach above Inkom to 6 feet/mile in the lower reach (Minshall and Andrews 1973).

The climate in the subbasin is semi-arid. Percentage of possible annual sunshine ranges from 53% to 72% with an annual average of 64% (National Weather Service, internet communication). Normal annual precipitation averages 12 inches at Pocatello. March, April, May, and November receive the highest amounts of precipitation (Table 1). Normal average temperature is 47.2°F (8.4°C) with an annual normal maximum of 59.3°F (15.2°C) and minimum of 33.4°F (0.8°C). Extreme temperatures range from -33°F (-36.1°C) to 105°F (40.6°C) (Table 2).

Vegetation in the Portneuf River subbasin is characteristic of semi-arid areas of the intermountain west. Most of the drainage is covered with grasses (*Poa* spp.), sagebrush (*Artemisia tridentata*), and juniper (*Juniperus utahensis*, Minshall and Minshall 1977). Higher elevations grow Douglas fir (*Pseudotsuga menziesii*), and aspen (*Populus tremuloides*). Willow (*Salix* spp.), dogwood (*Cornus stolonifera*), chokecherry (*Prunus virginiana*), rose (*Rosa woodsi*), and birch (*Betula occidentalis*) are common in the valleys.

Flows in the Portneuf River subbasin vary according to location but follow the general pattern of high spring flows and low flows in late summer-early fall. The hydrograph is highest in the springtime (i.e., March through June) coinciding with the melt off of snow at higher elevations (Table 3). Low flows occur from July to October. The diversion of water for irrigation affects flows throughout the irrigation season (mid-April to mid-September). Monthly mean flows for the Portneuf River at Pocatello range from 522 cfs in April to 95 cfs in August. An apparent loss of streamflow (about 87 cubic feet/second), probably to groundwater, from the Portneuf River and Marsh Creek occurs somewhere between the gaging stations at Topaz and McCammon and the gaging station at Pocatello (Norvitch and Larson 1970).

The construction of reservoirs within the subbasin, especially Chesterfield Reservoir (Figure 2) on the mainstem Portneuf River, has affected the annual hydrograph of high spring flows followed by late summer low flows. Typically, the reservoirs will be filled in the springtime decreasing the total flow during the peak runoff period. Stored water will then be released in late summer increasing the historical flow during that time period.

Some confusion exists surrounding the names of the reservoirs in the upper Portneuf River. The reservoir on the mainstem of the Portneuf River is called both the Chesterfield and Portneuf reservoir depending on the map or the person. The reservoir on Twentyfourmile Creek is called the Twentyfourmile or Chesterfield reservoir, again, depending on the map or person.

Presently, most people know, and the USGS identifies, the reservoirs on the mainstem Portneuf River as Chesterfield Reservoir and on Twentyfourmile Creek as Twentyfourmile Reservoir. This report will use the same naming convention - Chesterfield and Twentyfourmile reservoirs.

2.1.1 Watershed Characteristics

Eighteen waterbodies in the Portneuf River subbasin are on the 303(d) list. In addition to the mainstem Portneuf River, other major watersheds within the subbasin include: Mink, Rapid, Marsh, Dempsey, Pebble, and Toponce creeks (Figure 1). All of these watersheds/waterbodies are on the 303(d) list (Table 4). Other waterbodies on the 303(d) list include: Pocatello, Gibson Jack, Walker, Bell Marsh, Goodenough, Garden, Hawkins, Birch, and Cherry creeks. Hawkins Reservoir is the only 303(d)-listed reservoir.

Physical changes from higher to lower elevations are similar amongst the streams. Most of the streams originate in montane areas, usually Forest Service land. Based on site data from the Division of Environmental Quality's Beneficial Use Reconnaissance Project, the higher elevation stream sections tend toward higher gradients, lower sinuosity, Rosgen A-channel types, and V-shaped valley types (Table 5). Pool to riffle ratios are low (i.e., riffles predominate) and stream substrate tends toward a cobble surface (Table 6; Crist and Holden 1988). At lower elevations, mostly private land, the streams decrease in gradient and increase in sinuosity. Rosgen channel types are usually C, F, or G, within flat or trough shaped valleys. Width to depth ratios vary substantially with lower ratios usually found at higher elevations (Table 7). The BURP effort recorded very few pools within their monitoring sites resulting in low pool to riffle ratios. Bank vegetation and stability varied by site with no obvious trend. Lower values representing less protection or stability were observed in the mainstem Portneuf in the Downey Canal section and Pocatello, Indian, Walker, Goodenough, Garden, Arkansas, Hawkins, Cherry, Robbers Roost, Harkness, Dempsey, and Twentyfourmile creeks.

Human activity has had a significant impact on the mainstem Portneuf River. In the lower Portneuf River, construction of the 1.5 mile concrete channel through the City of Pocatello in the 1960s eliminated fish and wildlife habitat and created a migration barrier for trout accessing City Creek for spawning (U. S. Army Corps of Engineers 1992). As a result of the project, channel length was reduced by 4.1 miles and riparian habitat by 144 acres. The concrete channel represents 15% of the length of the Portneuf River for the segment from Johnny Creek to Interstate 86. The upper Portneuf River runs through the 7.8 mile Downey Canal, built in conjunction with the Chesterfield Reservoir. Diversions of the river through the canal eliminated about 16 miles of the Portneuf River. An engineering survey in 1991-1992 of the Downey Canal revealed that 3,500 feet of streambank had severe stability problems, 8,000 feet had moderate stability problems, and 4,500 feet had slight stability problems (Soil Conservation Service 1993). The survey also noted that 4,300 feet of the canal had stream gradients that could lead to serious channel erosion.

A reconnaissance survey by the Natural Resources Conservation Service (NRCS) on the approximately 13.5 miles of Portneuf River between Lava Hot Springs and McCammon revealed streambank conditions to be 33% poor, 27% fair, 8% good, and 32% excellent (Portneuf Soil and

*represents area of reservoir in acres

Water Conservation District 1996). Streambanks in fair or poor condition totaled 77,520 ft (14.7 miles). The Portneuf River below Dempsey Creek to the Portneuf-Marsh Valley Canal diversion was characterized as having vertical banks, with a lack of vegetation for building banks, and lacking large woody debris for in-stream cover for fish. The river below the diversion was less impacted by bank problems than upstream.

As part of the same survey, the NRCS also evaluated the streambank condition of smaller tributaries to the Portneuf River in the Lava Hot Springs to McCammon reach. East and West Bob Smith creeks had some areas that had downcut approximately 2 ft due probably to cropped fields which have changed the hydrology of the watershed by increasing runoff. The area of the creeks within the Portneuf River watershed were severely overgrazed. In Dempsey Creek, the lower 14,000 ft of streambank was in poor condition mostly due to livestock concentration on small pastures. Middle Dempsey Creek has also been affected by livestock such that 15,600 ft of streambank is in fair to poor condition. In upper Dempsey Creek, 47,200 ft of streambank along the 59,000 ft of channel was in fair or poor condition. From a fish habitat perspective, a visual estimation on the lower four miles of Dempsey Creek revealed that 50% of the banks do not support habitat for fish.

Streambanks/riparian areas have also been evaluated in other tributaries to the Portneuf River. Gore (1986) noted that riparian areas of Marsh Creek near McCammon, Portneuf River from McCammon to Lava Hot Springs, and the Downey Canal had all been degraded. Almost two-thirds of the 1.5 miles of Twentyfourmile Creek below the dam is in poor vegetative condition due to livestock use while the remainder is in fair to good condition (Soil Conservation Service 1993).

The Caribou National Forest has evaluated the stream channel stability and fish habitat condition of numerous streams on the forest. All 303(d)-listed streams in the survey rated good to excellent except Walker Creek, South Fork Hawkins Creek, and Middle Fork Cherry Creek (Table 8; Caribou National Forest 1983). Habitat in Mink, Bell Marsh, Walker, and Cherry creeks was in stable condition, though below potential (Caribou National Forest 1992a). Fisheries habitat in the mainstem Mink Creek from Cherry Springs to the Forest Boundary was considered poor (Lee Leffert, Caribou National Forest, personal communication).

The Caribou National Forest also collected water quality and macroinvertebrate information from the late 1970s to the mid-1980s. From water quality monitoring conducted from 1977 to 1982 on the South Fork and West Fork of Mink Creek, the Forest Service tentatively concluded the following: nitrogen was not a problem; fecal coliform was present; and turbidity and suspended sediment indicated the streams are generally clean (Lee Leffert, Caribou National Forest, personal communication). Overall, water quality was considered to be "good" in South Fork and "excellent" in West Fork. Macroinvertebrate information showed some degradation of water quality as South Fork rated only "poor" to "fair" while West Fork rated "good" with indication of some organic enrichment. Although the water quality of Toponce and Pebble creeks was not monitored, the Caribou National Forest (1992b) noted that the water quality was sufficient to support and maintain a coldwater fishery.

In the late 1970s, the Bureau of Land Management (BLM) evaluated habitat conditions for fish in various creeks on BLM land including Walker, Bell Marsh, Goodenough, Garden, and Birch creeks and the Left Hand Fork of Marsh Creek (Table 9; BLM 1980). Overall, 51% of the trout habitat was in poor to fair condition in 1978.

In 1993, the BLM conducted fish habitat surveys (2 sites per stream) on those sections of Walker and Goodenough creeks which pass through BLM land (Pat Koelsch, BLM, personal communication). Walker Creek below the South Fork confluence had a stable channel with only limited signs of excessive degradation or lateral movement. Overall riparian condition was considered good with a stable trend. Above the South Fork confluence, the creek channel stability was rated excellent with a riparian condition of good to excellent with a stable or slow upward trend. Goodenough Creek, above Mormon Canyon, had a relatively stable channel with only limited signs of excessive degradation or lateral movement. The riparian condition was rated good to excellent with an upward trend. Conditions of Goodenough Creek above the campground were similar to those observed at the other site above Mormon Canyon. The BLM in 1996 assessed the condition of that portion of Bell Marsh Creek flowing through BLM land. The stream was considered to be properly functioning but at risk (Geoff Hogander, BLM, unpublished data).

Some 303(d)-listed streams show evidence of unstable streambanks. Crist and Holden (1988) in their survey of streams on Ceded Lands of the Shoshone-Bannock Tribes observed over 30% eroding streambanks in South Fork Mink Creek, Walker Creek, and Toponce Creek (Table 6).

Salmonid spawning is listed as one of the beneficial uses of most of the 303(d) listed streams in the Portneuf River subbasin (Table 10). Cutthroat trout (*Oncorhynchus clarkii*) and mountain whitefish (*Prosopium williamsi*) are the only salmonids (i.e., trout, char, whitefishes) native to the Portneuf River (Simpson and Wallace 1982). Mohr (1968), in his investigation of the fishes of the Portneuf River and tributaries, found three introduced salmonid species - brown trout (*Salmo trutta*), rainbow trout (*O. mykiss*), brook trout (*Salvelinus fontinalis*).

The Portneuf River has a history of having an excellent trout fishery. In 1968 the upper Portneuf River was designated a blue ribbon river by the Idaho Department of Fish and Game (Portneuf Soil and Water Conservation District and Caribou Soil Conservation District 1988). Much of the trout fishery has been supported by rainbow trout, both wild and hatchery fish (Heimer et al. 1987).

The lower Portneuf River has not had the distinction of a blue ribbon trout fishery but nevertheless does support salmonids. Broderick et al. (1989) captured wild and hatchery rainbow trout, rainbow x cutthroat (hybrid) trout, brown trout, and mountain whitefish in the vicinity of the Pocatello waste water treatment plant.

Some tributaries may play an important role as nursery areas for mainstem trout populations. IDFG (Idaho Department of Fish and Game) found that recruitment of cutthroat and rainbow trout juveniles from Toponce, Twentyfourmile, and King creeks was virtually nonexistent

due to passage barriers (e.g., irrigation diversions, dewatering of the stream) or poor habitat (Heimer et al. 1987). Although recruitment of salmonid juveniles from Pebble is not documented, IDFG did emphasize the critical importance of maintaining existing trout particularly cutthroat, populations in light of the marginal quality of spawning habitat in mainstem Portneuf River.

Information on the presence of salmonid species is plentiful. The Shoshone-Bannock Tribes surveyed fish populations in Ceded Lands on the Caribou National Forest in 1986 and Holden 1988). Twenty-one of the sampled streams contained trout; twenty streams either dry or contained no fish (Table 11). Heimer et al. (1987) documented trout in P Springs, King, and Toponce creeks but found no trout in Twentyfourmile Creek.

2.1.2 Cultural Characteristics

Land ownership includes private, federal, state, and tribal (Figure 5). Almost 60% land within the subbasin is privately owned (Table 12). The largest landowners in the subbasin are the Caribou National Forest, Shoshone-Bannock Indian Tribes, and Bureau of Land Management.

Agricultural, range, forest, and urban are the major land uses in the subbasin (Figure 5). More than half of the subbasin is rangeland (Table 13). Much of the forest and rangeland is within the Caribou National Forest. Major crops grown in the Portneuf River subbasin include wheat, barley, potatoes, and hay (Ozburn and Modersitzki 1986; McNabb 1987). Beef cattle form the major livestock industry within the subbasin.

The majority of the Portneuf River subbasin is contained within Bannock and Caribou counties (Figure 2). Bannock County is the larger county in terms of population (Table 14). Both counties have shown an overall population increase since 1950 although Caribou County experienced a population decline in the 1980s. Caribou County has a higher proportion of its population as compared to Bannock County. Incorporated cities and towns, with 1996 Census population estimates, include: Pocatello (51,344), Chubbuck (8,876), McCammon (7,877), Downey (626), Lava Hot Springs (442), Bancroft (418), and Arimo (306).

Overall per capita income measured as a percent of U.S. per capita income is lower than the national average. There are two explanations why Bannock and Caribou counties are below the national average: relatively low wages and large family size (Benson and 1995).

Employment and earnings within the subbasin vary. For example, about two-thirds of employment in Bannock County in 1992 was in the retail trade, services, and government (Table 15). Sectors with the highest earnings for the county were the services, government, transportation, communication, and public utilities. Employment is not as concentrated in Caribou County as 10% of the jobs can be found in each of six sectors. Earnings on the other hand are concentrated in two sectors, mining and manufacturing, which account for almost half the earnings in Caribou County.

As of June 1997, there were nine facilities with National Pollution Discharge Elimination System (NPDES) permits to discharge into the Portneuf River (Table 16). All the facilities are located at or downstream of Lava Hot Springs. Most of the facilities are located in the Pocatello area (permits ID-000022-1, ID-000072-8, ID-002178-4, ID-002395-7, and ID-002716-2). Facilities include three waste water treatment plants and two fish hatcheries.

There are three current or historic Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA or Superfund) sites within the Portneuf River subbasin (Boyd Roberts, Division of Environmental Quality, personal communication). All three are located in or near the city of Pocatello. The Union Pacific Railroad Sludge Pit site contained sludge contaminated by heavy metals, volatile organic compounds, and semi-volatile organic compounds. The second site, McCarty's/Pacific Hide and Fur, was contaminated by PCBs and lead. Contaminated soils at both sites have been removed. The final site, Eastern Michaud Flats, includes the FMC and Simplot phosphate ore processing facilities. The site contains numerous contaminants associated with the processing of phosphate ore including radionuclides. The Sludge Pit has been delisted and is no longer a Superfund site while the McCarty's/Pacific Hide site is in the process of being delisted (Gordon Brown, Division of Environmental Quality, personal communication).

There are several reservoirs in the Portneuf River subbasin. The largest is Chesterfield Reservoir (1,245 acres) in the upper drainage (Table 17). The reservoir and Downey Canal were built in 1908-1912 to provide a dependable source of irrigation water for Marsh Valley farms (Soil Conservation Service 1993). Also in the upper drainage is Twentyfourmile Reservoir (34 acres). Both Wiregrass (4 acres) and Hawkins (68 acres) reservoirs are in the Marsh Creek drainage. Hawkins is the only reservoir on the 303(d) list.

Over 90,000 acres in the Portneuf River subbasin are irrigated. Acreage sprinkled versus flood irrigated is roughly equal (Table 13). Ten canal companies in the subbasin have water rights ranging from 6 cfs to 176 cfs (Table 17). The Portneuf-Marsh Valley Canal Company and the Chesterfield Canal and Reservoir Company store irrigation water in the Chesterfield and Twentyfourmile reservoirs, respectively.

Numerous groups are presently working to improve water quality in the Portneuf River (Table 18). They include government, quasi-government, civic, non-profit, and volunteer organizations in addition to private companies.

2.2 Water Quality Concerns & Status

EPA through its Index of Watershed Indicators (IWI) rates the Portneuf River subbasin at 5 on a scale of 1 to 6 with a score of 6 indicating subbasins with the most serious water quality problems (EPA, internet communication). The most serious problems as identified by the IWI are attainment of beneficial uses, wetland loss, agricultural runoff, and population change.

Problems in the Portneuf River have been recognized for several years. Ozburn and Modersitzki (1986) wrote that uses of the Portneuf River for recreation, drinking water supply, agricultural water supply, and a healthy fishery are impaired by sediment, nitrogen, turbidity, phosphate, and bacteria inputs into the stream.

The effect of diminished water quality is often first realized within the local fish population. For example, cutthroat and rainbow trout are considered highly intolerant to water quality degradation, whereas common carp (*Cyprinus carpio*) have a high tolerance of degraded water quality (Chandler et al. 1993). Evermann (1896, cited in Mohr 1968) reported that in Mink Creek "we found the cutthroat trout to be quite abundant." At least by the mid-1960s cutthroat trout were "not very abundant in the Portneuf River" according to Mohr (1968) in his investigation of the fishes of the Portneuf River and tributaries.

In 1991, IDFG revisited a site in the upper Portneuf River which had been electrofished annually from 1979 to 1987 (Scully et al. 1993). The densities in 1991 of both wild cutthroat and rainbow trout were less than 0.1 fish/100 m², a substantial decrease from previous high densities of over 1.5 wild rainbow trout and 0.5 wild cutthroat trout per 100 m² collected from 1984 to 1986. The decline was attributed to a decrease in spawning success and overall survival associated with severe sedimentation and very low flow.

IDFG also electrofished 2 miles of Marsh Creek through the Arimo Ranch area. Seventy-three percent of the fish stocked were suckers (letter from Richard Scully, IDFG, to Janet Waters, Portneuf Soil and Water Conservation District, 5 June 1998). Only 13 (3%) of the 478 fish captured were trout or whitefish.

An increase in the abundance of carp is indicative of a decrease in water quality. Mohr (1968) found no carp present in his investigation of nine sites on the mainstem Portneuf River. Thirty years later, carp were abundant enough that Maret (1997) reported that the high incidence of carp in a coldwater stream like the Portneuf River to be a strong indication of habitat degradation. Degradation in the Portneuf River includes habitat changes caused by sediment (Portneuf Soil and Water Conservation District 1996).

Water quality degradation can also be seen in macroinvertebrate communities. Sampling of macroinvertebrates by Minshall and Andrews (1973) throughout the Portneuf River and by Ecology Consultants (1977) in the lower Portneuf River indicated that the fauna has been greatly influenced by irrigation activities, runoff from agricultural lands, increased sediment and turbidity, and stream alteration. A comparison of invertebrate drift in 1979 and 1988 at two sites in the upper Portneuf River showed an overall substantial decline in both numbers of individuals and taxa (Mende 1989). Ecology Consultants (1977) also sampled periphyton in 1977 and found primarily pollutant tolerant algae inhabiting the lower Portneuf River.

2.2.1 Water Quality Limited Segments Occurring in the Subbasin

The 1994 303(d) list identified 27 water quality limited segments found in 18 waterbodies in the Portneuf River subbasin (Figure 1). Three streams have multiple segments listed (Table 19). Listed segments within the mainstem Portneuf River actually overlap. One segment, the longest, stretches between Chesterfield and American Falls reservoirs. The other eight segments cover the entire length of the Portneuf River from the headwaters to American Falls Reservoir. Garden Creek is split into two segments at the Garden Creek Gap. Both Hawkins Creek from headwaters to mouth and Hawkins Reservoir are listed.

Sediment and nutrients are the predominant pollutants on the 303(d) list for the Portneuf River (Table 19). All stream segments are listed for sediment and almost half of the streams are listed for nutrients. Other recognized pollutants include dissolved oxygen in Hawkins Reservoir and bacteria, oil and grease, and flow alteration in the mainstem Portneuf River.

2.2.2 Applicable Water Quality Standards

Waterbodies (stream segments and reservoirs) are listed as water quality limited because they do not support one or more of their beneficial uses. There are ten recognized beneficial uses by the State of Idaho which include stream biota, salmonid spawning, contact recreation, water supply, wildlife habitat, and aesthetics (Table 10). All waterbodies are considered to support industrial water supply, wildlife habitat, and aesthetics. Coldwater biota, secondary contact recreation (e.g., fishing), and agricultural water supply are recognized and existing beneficial uses for all the 303(d) listed waterbodies in the Portneuf River subbasin. Most of the waterbodies should also support salmonid spawning and some are large enough to be used for primary contact recreation (e.g., swimming).

For a waterbody to support its recognized beneficial uses, it must meet certain criteria. These criteria are set forth by the State of Idaho as water quality standards (Idaho Department of Health and Welfare no date available [nda]). As expected, these standards differ according to beneficial use (e.g., fecal coliform standards are more stringent for primary contact recreation than for secondary contact recreation). The standards can be either numeric or narrative. Temperature, dissolved oxygen, turbidity, and fecal coliform are examples of parameters for which numeric standards exist (Table 20). Standards may differ according to the beneficial use. For example, to meet the beneficial use for cold water biota, a stream should not exceed an instantaneous temperature of 71.6°F (22°C) or fall below a dissolved oxygen level of 6.0 mg/l; warm water biota require instantaneous temperatures less than 91.4°F (33°C) and dissolved oxygen greater than 5.0 mg/l (Idaho Department of Health and Welfare nda). Other numeric standards have been established for pH, dissolved gas, chlorine, toxic substances, ammonia, intergravel dissolved oxygen, and radioactivity (Appendix A).

Narrative criteria exist for hazardous and deleterious materials; toxic substances; floatable suspended, or submerged matter; excess nutrients; oxygen-deinforcing materials; and sediments (Idaho Department of Health and Welfare nda). All the narrative standards follow similar

Table 19. Water quality limited segments in the Portneuf River subbasin on the 303(d) list.

*criteria for streams, criteria for lakes and reservoirs differ

**above background

wording in that criteria exceedances occur when designated beneficial uses are impaired. Radioactive materials also have narrative criteria based on 10 CFR 20.

Sediment and nutrients are the two most recognized pollutants in southeast Idaho judging from the 303(d) list of water quality limited streams, yet neither has a numeric standard. How then can it be determined that the present level of sediment or nutrients is impacting beneficial use? Targets can be established based on literature that has examined the effect of various levels of sediment or nutrients on stream biota or salmonid spawning. As an example, DEQ has compiled sediment targets for consideration in writing total maximum daily loads (Table 21). Although some of the targets (i.e., turbidity and intergravel dissolved oxygen) actually correspond to water quality standards, it should be stressed that most of the targets are not standards and are not legally binding. For phosphorus, EPA (1986) recommended that a desired goal for the prevention of plant nuisances in streams not discharging directly to lakes or impoundments is a level not to exceed 0.10 mg/l total phosphorus: total phosphates as phosphorus should not exceed 0.05 mg/l in any stream at the point where the stream enters a lake or reservoir (e.g., Portneuf River entering American Falls Reservoir).

2.2.3 Summary and Analysis of Existing Water Quality Data

Waterbodies appear on the 303(d) list because they are considered to not support their beneficial uses. Few of the many reports on the Portneuf River speak directly to the support of beneficial uses.

Gore (1986) qualitatively evaluated the water quality in the mainstem Portneuf River from McCommon to the Downey Canal. He rated water quality from McCommon to Lava Hot Springs as poor due to land management practices; this section is also seasonally dewatered. Water quality was considered good from Lava Hot Springs upstream to the Downey Canal. In the Downey Canal reach, high turbidity and lack of riparian vegetation contribute to poor water quality.

The Division of Environmental Quality (DEQ) initiated the Beneficial Use Reconnaissance Project (BURP) in 1994 with the intention of determining whether waterbodies listed on the 303(d) list were actually supporting their beneficial uses (Division of Environmental Quality 1996a). Data collected on biological, physical, and chemical parameters were used to assess this support (Appendix B; Division of Environmental Quality 1996b). BURP monitoring confirmed that the mainstem Portneuf River, Rapid Creek, Walker Creek, Hawkins Creek, and Dempsey Creek were not supporting at least one of their beneficial uses (Table 22). Further information is needed to determine if Pocatello, Marsh, Birch, Cherry, and Twentyfourmile creeks are supporting their beneficial uses. Based on BURP analysis Gibson Jack, Mink, Bell Marsh, Goodenough, Garden, Pebble, and Toponce creeks are supporting their beneficial uses.

In addition to the 303(d) listed streams undergoing BURP monitoring, several non-listed streams were also evaluated (Table 23). Streams which are not supporting at least one beneficial use include Indian and Arkansas creeks. City and Jackson creeks require more information to determine the support status of their beneficial uses.

Table 21. Sediment targets for consideration in writing Total Maximum Daily Loads (from et al., unpublished document). Max = maximum, avg = average, and min = minimum.

Parameter	Possible target
Turbidity	<= 50 NTU, instantaneous, or <= 25 NTU for > 10 calendar days above background*
Light penetration	should not reduce the depth of the compensation point photosynthetic activity by > 10% from the seasonal established norm for aquatic life
Intergravel dissolved oxygen	>= 5.0 mg/l, 1-day min, or >= 6.0 mg/l, 7-day avg max
Total suspended solids	<= 50 mg/l, avg monthly value, with max daily value <= 80 mg/l
Riffle stability	<= Riffle Stability Index of 70
Subsurface sediment	for streams with subsurface sediment < 27%, do not exceed existing fine sediment volume level for streams with subsurface sediment > 27%, reduce subsurface sediment to <= 27%, 5-year avg, with n individual year > 29%
	concentration of subsurface sediment < 0.85 mm <=

* same as Idaho's water quality standard

Summer thunderstorms can influence water quality. McSorley (1977) reported that a summer thunderstorm in the Marsh Creek watershed that produced five percent of the annual precipitation increased the total solids concentration at one site to 15,000 mg/l, the highest recorded for any southeast Idaho stream to that time.

The following is a discussion by identified pollutant in the Portneuf River subbasin. For each pollutant, a summary analysis of existing data and inventory of sources is presented. Data gaps are also identified.

Flow Alteration

Summary Analysis

Flow alteration can have substantial impacts on aquatic biota. Minshall and Andrews (1973) did not look at flow alteration directly, but did note a decrease in the volume of flow in the Portneuf River with progression downstream during irrigation season. They postulated that such practices would be expected to influence stream biota by reducing habitat during an important fish production period, and increasing water temperature and decreasing dissolved oxygen content in the river at an already critical time of the year. In some years virtually all the water in the Portneuf River at the Portneuf-Marsh Valley Canal has been diverted. Loss of water along with high temperatures puts a stress on aquatic organisms in this section of the river between Topaz and Marsh Creek (McSorley 1977).

Flow alteration is a listed pollutant for the section of the Portneuf River from the downstream point of the Downey Canal (aka Chesterfield Canal) to Lava Hot Springs. However, it is DEQ's position that flow alteration, while it may adversely affect beneficial uses, is not a pollutant per section 303(d) of the Clean Water Act. There are no Idaho water quality standards for flow, nor is it suitable for estimation of load capacity or load allocations. Because of these practical limitations, TMDLs will not be developed to address flow alteration.

For many of the water quality limited waters on Idaho's 303(d) list, this position will have little effect on implementation plans. This is because concerns which resulted in a listing for flow alteration are often reflected in listed pollutants - sediment or temperature, for example. In such cases, actions taken to address these related pollutants will likely address flow as well. In other cases, alternate control strategies would be applied outside the TMDL process.

Dissolved Oxygen

Summary Analysis

Only Hawkins Reservoir has dissolved oxygen listed as a pollutant of concern (Table 19). Reservoirs, because of low flow and the presence of significant aquatic vegetation, are more prone to low levels of dissolved oxygen than streams. Often these low levels of oxygen occur at

night in lakes and reservoirs when aquatic vegetation is using oxygen rather than producing oxygen. The Idaho water quality standards recognize the difference between lotic (i.e., stream and lentic (i.e., lakes and reservoirs) through different standards: the minimum of 6.0 mg/l of dissolved oxygen for support of cold water biota does not apply to the lower depths of lakes and reservoirs (Idaho Department of Health and Welfare nda).

Data on dissolved oxygen levels in Hawkins Reservoir are limited to instantaneous information. Idaho Department of Fish and Game (IDFG) surveyed the reservoir in 1991 and found a consistent 8.0 mg/l of dissolved oxygen (Table 24), well above the cold water biota standard of 6.0 mg/l. DEQ sampling of the water column at one site in the reservoir in August 1997 found dissolved oxygen levels of about 4.0 mg/l near the bottom. These measurements do not exceed the water quality standards as the 6.0 mg/l standard for cold water biota does not apply to the bottom 20% of water depth in natural lakes and reservoirs where depths are 35 meters or less (Idaho Department of Health and Welfare nda).

Fish kills can be an indication of low dissolved oxygen and are usually the most pronounced effect dissolved oxygen has on beneficial uses. Fish kills in Hawkins Reservoir occurred in 1989 and 1991 (Jim Mende, Idaho Department of Fish and Game, personal communication). The 1989 kill occurred in late summer while the 1991 happened in the winter. Data collected by IDFG in January 1993 indicated low dissolved oxygen levels throughout the Reservoir (Table 24). According to Jim Mende, operation of the reservoir has changed in the several years as operators have tried to keep more water in the reservoir. Coincidentally or not there has been no report of a fish kill in at least the last three years.

Hawkins Reservoir was built in the early 1900s (Centennial Committee of Arimo 1990) for the purpose of providing irrigation water for downstream users (IDWA 1971). As the dam construction preceded implementation of the Clean Water Act, the dam is considered a preexisting condition. The dam exists to provide water to downstream users and will, in some water years, be drawn down. Such conditions may lead to dissolved oxygen problems.

Limited regular monitoring of streams in the Portneuf River subbasin for dissolved oxygen does not indicate low dissolved oxygen levels. Instantaneous dissolved oxygen levels at USGS surface-water stations did not fall below 6.0 mg/l, the minimum required for support of cold water biota (Table 25). The lowest dissolved oxygen level recorded in quarterly monitoring of Mini Creek was 6.8 mg/l (Table 26). Recent sampling by the City of Pocatello in the lower Portneuf River has shown dissolved oxygen levels dipping below the 6.0 mg/l standard (Jim Brock, Raj Creek Research, Inc., personal communication).

Pollutant Sources

Dissolved oxygen problems in lentic waters usually stem from high levels of aquatic vegetation (macrophytes or phytoplankton) which in turn are a good indication of higher level nutrient (e.g., nitrogen and phosphorus) input. DEQ did note both emergent and submerged macrophytes throughout the reservoir in the August 1997 reconnaissance monitoring of Hawkins Reservoir. Although not a "source" of pollution, operation of the reservoir could set the

Table 24. Temperature and dissolved oxygen data in Hawkins Reservoir from Idaho Department of Fish and Game (IDFG) sampling in July 1991 (from Scully et al. 1993), IDFG sampling in January 1993 (Dick Scully, IDFG, personal communication), and Idaho Division of Environmental Quality (DEQ) sampling in August 1997.

conditions for dissolved oxygen to be a concern. It appears that changing the operation of the reservoir may have improved dissolved oxygen conditions.

Many conditions, alone or in conjunction with other factors, can result in low dissolved oxygen within the flowing reaches of the Portneuf River subbasin. In addition to abundant aquatic vegetation, these conditions include flow alteration (Minshall and Andrews 1973) and stormwater runoff (Brock 1989). Flow alteration can result in increased stream temperatures. Saturation levels of dissolved oxygen decrease as temperature increases. Stormwater runoff can input organic material or chemicals into the stream which have an "oxygen demand" which low the oxygen level in the receiving water.

Data Gaps

The extant data on dissolved oxygen in Hawkins Reservoir is limited to instantaneous measurements. No information is available on a periodic daily, or diurnal, basis especially during late summer - a time when low dissolved oxygen levels are most likely to occur. Information on nutrient loading into the reservoir is also sparse.

Oil and Grease

Summary Analysis

Oil and grease have been identified as pollutants for that segment (Johnny Creek to Interstate 86) of the Portneuf River which flows through Pocatello (Table 19). The Southeast Idaho Council of Governments in their study of water quality in Bannock and Caribou counties recognized oil as a major contaminant in municipal stormwater runoff directly discharged into Portneuf River (Hancock and Bybee 1978). Oil and grease are petroleum hydrocarbons which affect aquatic life through asphyxiation of fish through coating of gill surface or macroinvertebrates when floating masses of oil and grease coat surface debris which settles on bottom of the waterbody (EPA 1986). High levels of oil and grease can also cause fish kills if biochemical oxygen demand.

Little information on oil and grease in the Portneuf River was found. Perry et al. (197 sampled for oil and grease in the lower Portneuf River (upstream limit was Portneuf River-M Creek confluence), and although no data was presented, there was no discussion as to oil and grease being a problem in the Portneuf River. Limited monitoring of Pocatello stormwater discharge was conducted in 1979 (Division of Environment 1980) and in 1994 (Candy Ross, City of Pocatello, personal communication); however, in neither case was sampling or analysis done specifically test for oil and grease.

Pollutant Sources

Oil and grease are commonly found in urban/suburban runoff (Horner et al. 1994) such as stormwater drains. Agricultural runoff can also be a source of petroleum hydrocarbons (M-

1997) which are used as pesticides, herbicides, parasiticides, or carriers for other agriculture-related chemicals (Farm Chemicals Handbook 1995).

Data Gaps

More data on the amount of oil and grease input and resultant effect on water quality in the Portneuf River is needed. Monitoring should include at a minimum the mainstem Portneuf River and stormwater runoff within Pocatello.

Bacteria

Summary Analysis

Bacteria are considered a problem in the Portneuf River mainstem from Chesterfield Reservoir to American Falls Reservoir (Table 19). The major effect of bacteria on beneficial uses is through their influence on human health in primary and secondary contact recreation or domestic water supply. Both fecal coliform and fecal streptococcus can have human health concerns (APHA et al. 1995). Water quality standards in Idaho exist only for fecal coliform (Idaho Department of Health and Welfare nds). Data on bacteria, mostly fecal coliform information, dates back to the 1970s (Appendix C).

Fecal coliform counts have exceeded state water quality standards for primary contact recreation numerous times since 1990. Southeastern District Health Department (unpublished data) monitoring showed exceedances in every year from 1990 to 1994 (Table 27; Figure 7; Appendix C). Exceedances were documented at least once from Lava Hot Springs to below Pocatello during the five-year period. Sampling by DEQ in September of 1991 also confirmed exceedances (downstream of Custer Street) in the Portneuf River within the city of Pocatello but found no exceedances in one day of monitoring the city's groundwater collection system and an actively discharging stormwater drain (DEQ, unpublished data). Most of the water quality exceedances were instantaneous exceedances. Instantaneous fecal coliform counts at USGS surface-water stations exceeded water quality standards in 1995 and 1996 at the Marsh Creek and Pocatello stations (Figure 8; Appendix C). The cause of these exceedances is unknown.

DEQ monitoring in 1998 documented exceedances of the fecal coliform standard for primary contact recreation in Mink Creek and lower Portneuf River, and for secondary contact recreation in Pocatello Creek (Appendix C). Although quarterly monitoring in Mink Creek indicated no instantaneous exceedances, further sampling following the August sample indicated exceedances of the 50 colonies/100 ml geometric mean standard. Samples in both Pocatello Creek and the Portneuf River through Pocatello showed exceedances of the instantaneous standard, the 10% standard, and the geometric mean standard in August and September monitoring.

There are no state water quality standards for fecal streptococci. USGS monitoring documented counts as high as 2,100 colonies/100 ml (Figure 9; Appendix C).

WATER QUALITY MONITORING REPORT

1990-1996 Water Quality Data Summary

Calculated from 100 ml samples

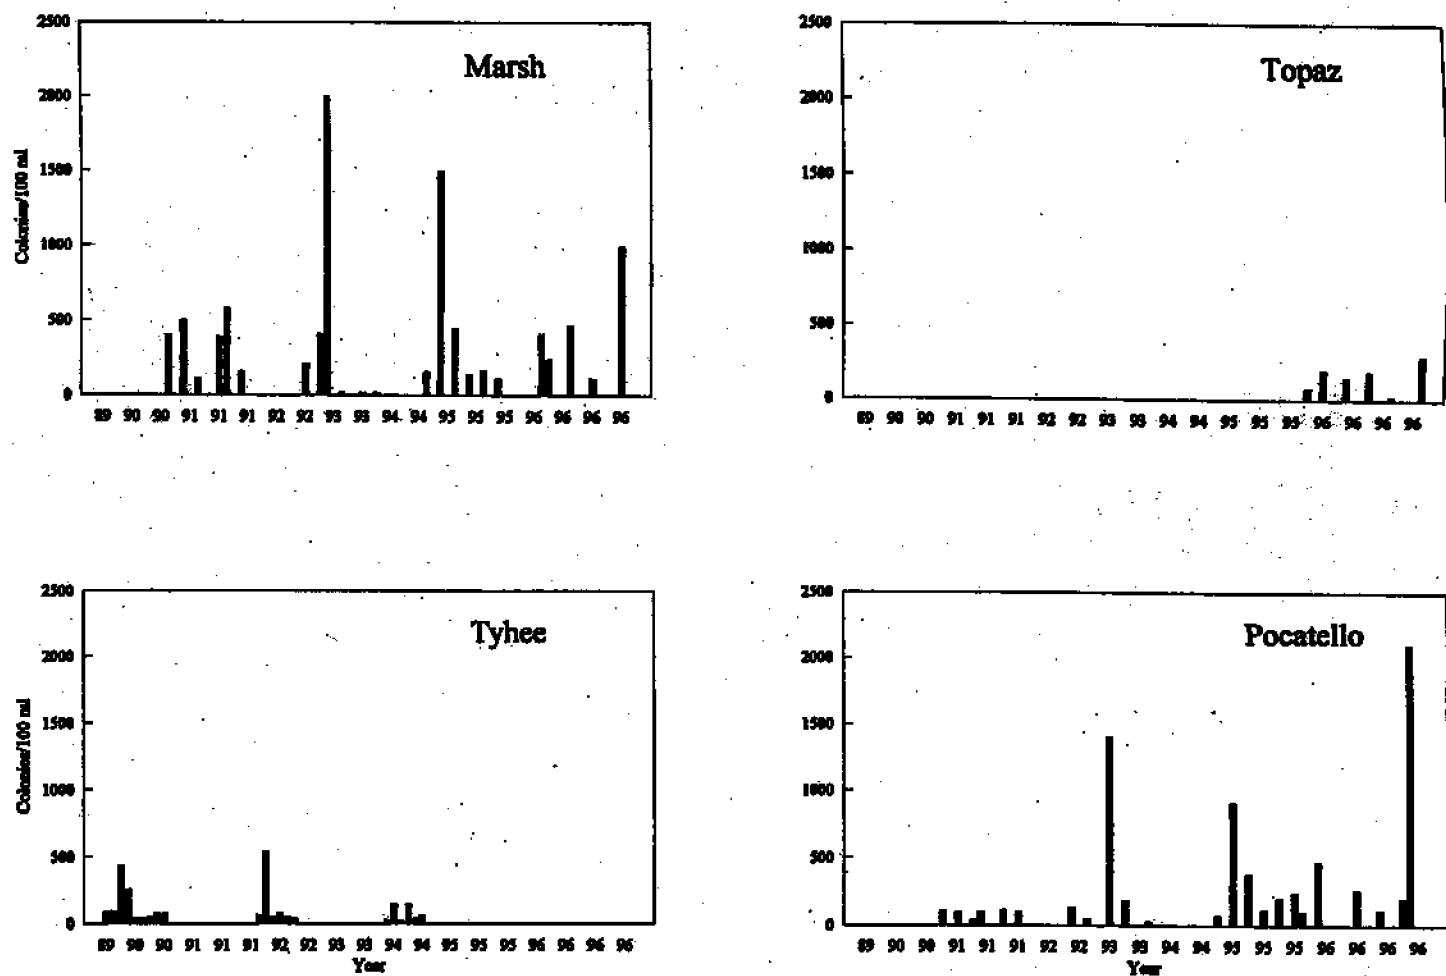

Figure 9. Fecal streptococci monitoring at USGS surface-water stations, 1989-1996.

Pollutant Sources

Several reports have identified sources of bacteria input into the Portneuf River. Hancock and Bybee (1978) noted that fecal coliform was a major contaminant in Pocatello's stormwater runoff into the Portneuf River. Livestock has also been recognized as a source of bacteria (Hoover 1985; Drewes 1987; Caribou Soil Conservation District 1991; Soil Conservation Service 1993). Marsh Creek has also been a source of bacteria into the Portneuf River (Perry et al. 1977; McSorley 1977; Frenzel and Jones 1985). Levels of bacteria exceeding state water quality standards were documented by Hoover (1985) in the mainstem Portneuf River below the Down Canal, Twentyfourmile Creek, Eighteenmile Creek, Toponce Creek. Hoover attributed all the bacterial pollution to livestock and waterfowl. Drewes (1987) found high levels of fecal coliform in Pocatello, Rapid, Jackson, and Indian creeks as well as runoff from several canyons (Appendix C) - all sources which could still be contributing bacteria to the Portneuf River. Sampling by DEQ in 1998 indicated that Mink Creek and, especially, Pocatello Creek contributed to the bacterial load in the Portneuf River (Appendix C).

Data Gaps

Information on fecal coliform input into the Portneuf River is more prevalent than information on fecal streptococci. Existing fecal streptococci data did not separate the enterococcus group, a more specific indicator of fecal contamination. Separation of the enterococcus group in future monitoring would provide an additional tool in evaluating fecal bacterial impacts.

Although substantial information does exist on bacteria loading in the Portneuf River, there is little data which points to input sources, a common "problem" in non-point source pollution. A sampling strategy which would help identify sources of bacterial contamination would be beneficial.

Sediment

Summary Analysis

Sediment is a significant problem in the Portneuf River. Suspended sediment and associated pollutants cause the major water quality problems in the Portneuf River and its tributaries (Ozburn and Modersitzki 1986). Mohr (1968) commented that the Portneuf River below Pocatello "is usually turbid year round."

Both tributaries and the mainstem are sources of sediment in the upper Portneuf River. Heimer and Ratzlaff (1987) contended that overland and streambank erosion were significant sources of silt into the Portneuf River. They looked at channel stability of sections of the upper Portneuf River (including the channelized section known locally as the Downey Canal), Topo Creek, and Twentyfourmile Creek. All the sections, except one, were rated as poor or fair (Table 28). In the same area, the Forest Service (Caribou National Forest 1985) estimated that sediments

*reaches listed downstream to upstream

**reaches within the channelized section of the Portneuf River (i.e., Downey Canal)

delivery in Toponce and Pebble Creek tributaries was 23 tons/year (0.002 tons/acre/year) and 20 tons/year (0.002 tons/acre/year), respectively. Hoover (1985) in his study of the upper Portneuf River watershed reported that Twentyfourmile Creek contributed the most sediment of any tributary by a factor of two. In two of the three tributaries that he monitored (Eighteenmile, and Toponce creeks), sediment yield doubled between upstream and downstream sites. Month of highest transport was in April with the greatest discharge of sediment at 378 tons/day measured in the mainstem Portneuf River just below the Downey Canal.

Sediment can degrade streams through deposition on streambed surfaces. Mende (1989) found depth fines (percentage of substrate by volume < 6.3 mm) at five sites in the upper Portneuf River to range from 32.9% to 82.2% with a median of 41.3%. Scully et al. (1993) examined the physical habitat of two mainstem Portneuf River sites in 1991. Both sites (upper site - between Pebble Creek and the downstream end of the Downey Canal; lower site - just downstream of Pebble Creek) had high levels of fines in the substrate composition and runs/pools were predominant. Maret and Ott (1997) sampled streambed sediment at both Pocatello (1992) and Topaz (1992-1994) surface-water stations. All samples were comprised of particles < 2 mm (i.e., sand, silt, or clay). Royer and Minshall (1997) observed a mean embeddedness level of 88% (SD=25%) at one mainstem Portneuf River site between Lava Hot Springs and Pebble Creek.

The Caribou National Forest estimated erosion for all the watersheds on the forest (Caribou National Forest 1985). Marsh Creek had the highest erosion rate on the forest. Rates on the upper and lower Portneuf were only slightly lower (Table 29).

The primary sources of sediment in Marsh Creek are tributaries streams on the west bench. Merrell and Onstott (1965) observed that the area west of Marsh Creek between Garden Creek and Marsh Creek's confluence with the Portneuf River has eroded much more severely than any other part of the Portneuf River subbasin (Table 30). McSorley (1977) estimated that during the 15-day runoff period in 1976 over 92,000 tons of total solids, which includes suspended sediment, were carried into Marsh Creek by the 19 west bench streams. As only 9,000 tons were estimated to have been carried into the Portneuf River during the runoff period, 83,000 remained in the Marsh Creek stream channel and floodplain. Walker, Bell Marsh, Garden, Hawkins, and Cherry creeks all showed high turbidity and calculated total suspended solids (TSS) values during the 1976 spring runoff period although most of the sediment input came from smaller streams (Table 31). During the remainder of the year, Marsh Creek contributed another 75,000 tons of sediment to the Portneuf River, much of which could have been the sediment previously deposited during the runoff period.

In addition to Marsh Creek, three other creeks - Rapid, Dempsey, and Pocatello - are also significant contributors of sediment to the Portneuf River (Drewes 1987). Monitoring data from November 1985 to July 1986 indicated that the three creeks contributed on the average 41.0, 31.3, and 10.0 tons/day of suspended sediment, respectively (Table 32; Appendix D). North Fork and South Fork Pocatello Creek had the highest average suspended sediment concentrations over the sampling period at 266 and 249 mg/l, respectively. The highest instantaneous concentration of suspended sediment was 1,690 mg/l in South Fork Pocatello Creek on 18 November 1985.

Table 32. Mean suspended sediment and sediment loading from cropland in subwatersheds in the lower Portneuf River subbasin, November 1985 to July 1986 (from Drewes 1987).

Subwatershed	Suspended sediment (mg/l)	Sediment (tons/day)	Sediment (tons/acre)	Acres of cropland	Total for period* (tons)
North Fork Pocatello Creek	266	10.0	1.09	2,125	2,316
South Fork Pocatello Creek	249	0.7	5.00	31	155
Sorrell Canyon	131	0.5	0.23	403	93
Indian Creek	112	0.9	0.28	921	258
Rapid Creek	101	41.0	0.77	12,273	9,450
Jackson Creek	110	1.6	0.68	549	373
Dempsey Creek	123	31.3	6.00	1,211	7,266

*sampling period 232 days

Highest loss of sediment from cropland was in Dempsey Creek at 6 tons/acre and South Fork Pocatello Creek at 5 tons/acre.

Quarterly monitoring in Mink Creek showed higher levels of total suspended solids during spring runoff as compared to other times of the year. TSS exceeded 100 mg/l in April compared to less than 15 mg/l in November, February, or August (Table 26).

Pollutant Sources

Sources of sediment input into streams in the Portneuf River subbasin include cropland and streambank erosion (Hoover 1985; Ozburn and Modersitzki 1986; Soil Conservation Service 1993) and municipal stormwater runoff (Hancock and Bybee 1978). About 80% of the dry cropland in the lower Portneuf River subbasin (downstream of Lava Hot Springs) has slopes over 12% with erosion rates at four times the maximum soil loss rate recommended for these soils (McNabb 1987). The predominant dryland crop rotation of grain/fallow which leaves the surface exposed during the fallow year can result in excessive erosion rates, especially on slopes greater than 20% (Portneuf Soil and Water Conservation District 1996). Erosion is also a problem in irrigated land with slopes that meet or exceed 4%. Sediment input from croplands has been monitored at least since the 1960s when Merrell and Onstott (1965) reported that sediment production in the Portneuf River subbasin is primarily from sloping, non-irrigated cropland. Roberts (1977) stated that non-irrigated cropland is the largest single contributor of sediment to waters in Bannock and Caribou counties adding 76% and 65%, respectively. The Soil Conservation Service (1979) estimated that of the 75,800 acres in dry cropland in Bannock County at that time, 67,200 acres (89%) exceeded the tolerable soil loss. In the Portneuf River subbasin above Topaz (between McCammon and Lava Hot Springs), essentially all of the cropland (about 33% of the area) has been identified as critical areas for sources of agricultural nonpoint source pollution (Portneuf Soil and Water Conservation District and Caribou Soil Conservation District 1988). Grazing activities also contribute to sediment problems in the Portneuf River subbasin (BLM 1980; Hoover 1985; Portneuf Soil and Water Conservation District and Caribou Soil Conservation District 1988; Soil Conservation Service 1993).

Other sources of sediment include occurrences of severe and rapid erosion on tributaries and draining of Chesterfield Reservoir, which acts as a sediment trap for all waters draining into it (Portneuf Soil and Water Conservation District and Caribou Soil Conservation District 1988). Rapid erosion events occurred in the Downey Canal in 1984 and in Twentyfoursmile Creek in 1985 (Scully et al. 1993). Draining of Chesterfield Reservoir and subsequent input of sediment into the Portneuf River took place in 1986 and 1992.

Roads can often be a source of sediment into streams. The Caribou National Forest, including areas of the forest outside the Portneuf River subbasin, has an estimated average road density of 1.07 miles of road/mi² (Randy Tate, Caribou National Forest, personal communication). However, this value includes all roads. If only roads classified as open roads are considered, there are 0.76 miles of road/mi².

Sediment produced in one subbasin can affect downstream subbasins. For example significant quantities of total solids are exported from Marsh Creek to the lower Portneuf (Perry et al. 1977). In turn, sediment produced in the Portneuf River subbasin eventually flows into American Falls Reservoir. Bechtel Environmental (1996) estimated that the Portneuf contributes less than 10% of the sediment load into the reservoir.

Control of sediment input into streams will also control other contaminants. Nutrients such as nitrogen and phosphate, and bacteria (Roberts 1977) as well as metals and pesticides (Terrene Institute 1994) from nonpoint sources often reach the stream attached to soil particl

Data Gaps

Much information is available on sedimentation in the Portneuf River subbasin for both mainstem Portneuf River and tributaries. Most of the data, however, is more than 10 years old. Current information is available from USGS but is limited to surface-water stations (i.e., Portneuf River at Pocatello and Topaz and Marsh Creek). The lack of recent data, for example, the last five years, does not account for changes (e.g., implementation of agricultural best management practices) which have reduced nonpoint source pollution since the last round of monitoring. Roberts (1977) reported that sediment yields from non-irrigated cropland, irrigated cropland, an rangeland and woodland in Bannock and Caribou counties were annually being reduced by 1.7%, 3.7%, and 2.1%, respectively. Such reductions, if seen year after year, would, after 20 years (i.e. 1997), have a substantial impact on the reduction of sediment into the Portneuf River and tributaries.

Nutrients

Summary Analysis

Nutrients affect beneficial uses directly (e.g., un-ionized ammonia can be toxic to fish) and indirectly (e.g., high concentrations of nitrogen and phosphorus, especially phosphate, can result in excessive aquatic growth). Nitrogen in the form of un-ionized ammonia can also be toxic to fish and other aquatic life. Brock (1989) documented an exceedance of state water quality standards for un-ionized ammonia in the Portneuf River below the Pocatello Sewage Treatment Plant's effluent discharge outfall. Excessive plant growth can lead to eutrophication which in turn affects drinking water, aquatic life, recreation, and aesthetics. During his 1988 and 1989 sampling of the lower Portneuf River, Brock (1989) observed fluctuations in dissolved oxygen levels over a 24-hour period. During the day when photosynthetic activity was high, dissolved oxygen levels were well above the state water quality standard of 6.0 mg/l for cold water biota. At night, however, when plants respire, dissolved oxygen levels in 1989 dropped below the 6.0 mg/l standard. Although, there are numerous factors which affect the concentration of oxygen in the lower Portneuf River, aquatic vegetation plays an important role. Campbell et al. (1992) concluded that high concentrations of phosphate in the Portneuf River have resulted in marked eutrophication in slow moving parts of the river and American Falls Reservoir.

Minshall and Andrews (1973) examined nutrient levels in the Portneuf River from Chesterfield Reservoir to below Pocatello. Nitrate values were highest during the winter, became reduced during the period of spring runoff, and declined progressively during the summer. Phosphate concentrations showed less of a seasonal trend but generally increased gradually from September through March and then declined during the growing season. Both nutrients, although phosphate to a lesser extent, followed the same general pattern of a downstream increase in concentrations. At certain times of the year (e.g., fall), nitrate appears to be the limiting factor for growth of aquatic vegetation as opposed to phosphate or carbon dioxide.

McSorley (1977) monitored nutrients in Marsh Creek. He found that total phosphorus and nitrates increased during the runoff period in 1976 to a greater extent than ortho phosphate or total Kjeldahl nitrogen (sum of organic nitrogen and ammonia nitrogen). He also noted that nitrates and ammonia decreased considerably between 1969 and 1975, most likely a result of the implementation of better farming practices in the area.

In the upper Portneuf River subbasin (upstream of Lava Hot Springs), the primary period of nutrient loss occurs during periods of increased overland runoff and snowmelt (Hoover 1985). The flow weighted average pounds per day of nitrate and phosphorus loss for the upper Portneuf River subbasin were 517 and 46 pounds/day, respectively, in 1985 (Table 33).

Watersheds in the lower Portneuf River monitored from November 1985 to July 1986 showed high levels of nutrient contributions into the Portneuf River (Drewes 1987). Phosphorus levels exceeded 0.1 mg/l of total phosphorus and 0.05 mg/l of ortho phosphate consistently throughout the sampling period. Drewes concluded that nitrogen compounds from these streams are not only a major pollutant in the creek of origin, but could also, under high flow conditions, such as summer thunderstorms, have a great impact on the Portneuf River and American Falls Reservoir.

Campbell et al. (1992) compared concentrations of ortho phosphate in the Portneuf River between 1972 and 1990-1991 and, generally, overall levels of ortho phosphate had not changed (Table 34). Levels of ortho phosphate in the Portneuf River increased as the river flowed through Pocatello. The authors suggested that an increase in ortho phosphate concentrations at the furthest downstream site (Siphon Bridge) is indicative of a new source of ortho phosphate in the reach such as the Pocatello Sewage Treatment Plant, Batise Springs, or phosphate-saturated bottom sediments. They concluded that the section of the Portneuf River at Siphon Road is experiencing significant eutrophication.

Monitoring in Mink Creek showed relatively consistent levels of total nitrate throughout the monitoring period while total phosphorus increased substantially during spring runoff (Table 26). Total nitrate levels ranged from 0.2 to 0.7 mg/l for the November 1997 to August 1998 period. Total phosphorus increased from less than 0.05 to 0.07 mg/l in February and August 1998 to about 0.2 mg/l in April of 1998 (November 1997 was ignored as the procedure was unable to detect levels less than 2.0 mg/l).

Table 33. Flow-weighted average pounds/day for nutrients by yearly average flow in the upper Portneuf River subbasin, March to October 1985 (from Hoover 1985).

Station	Nitrate	Nutrients in pound/day		
		Total Kjeldahl nitrogen	Total phosphorus	Ortho- phosphate

Hawkins Reservoir was sampled for nutrients in 1997 as part of DEQ's Beneficial Use Reconnaissance Project. Total Kjeldahl nitrogen measured 0.74 mg/l at a shallow depth site 0.90 mg/l at the deep depth site. At the two sites, total phosphorus was 0.09 mg/l in shallow water and 0.17 mg/l in deeper water. A concentration of total phosphorus of 0.09 mg/l places Hawkins Reservoir in Carlson's eutrophic range (Brian Hoelscher, Division of Environmental Quality, personal communication). However, chlorophyll a levels were low at 2.1 $\mu\text{g/l}$ and water clarity was good at 5.5 meters (Secchi depth). Both the chlorophyll level and water clarity are typical of a eutrophic waterbody.

Pollutant Sources

Rupert (1996) recognized several sources of nitrogen in his investigation of the upper Snake River basin. For the entire basin which includes the Portneuf River, 93% of the total nitrogen input was produced by cattle manure, fertilizer, and legume crops. Input of nitrogen similar for cattle manure, fertilizer, legume crops, and precipitation in the southeastern counties of the study area (including Bannock and Caribou counties).

Several other sources contribute nutrients to Portneuf River. Sampling of nearby springs and the mainstem Portneuf River in the Pocatello area in 1992 and 1993 by Bechtel Environmental, Inc. (1996) generally found high levels of nitrates, ortho phosphates, and total phosphorus when compared to upstream sites (Table 35). Perry and Clark (1990) sampled four spring "systems" in the lower Portneuf River and noted that Batise Spring System is nutrient rich and probably impacted by anthropogenic activity south of the springs. Total phosphorus and ortho phosphate were also found in mainstem river sediments. In addition to springs, Campbell et al. (1992) suggested that the Pocatello Sewage Treatment Plant and river bottom soil which had reached its saturation level for phosphates could be sources of ortho phosphates into the Portneuf River. Die-off of algae in Chesterfield Reservoir (Hoover 1985), and other reservoirs, can also increase nitrogen in downstream sections of the Portneuf River. Stormwater runoff into the Portneuf River can also be a source of nitrogen and phosphorus (Division of Environment 1980).

In 1988 and 1989, Brock (1989) studied the Portneuf River in the vicinity of the Pocatello waste water treatment plant. He found that the plant was generally discharging effluent that had higher concentration (up to 100 times higher) of ammonia than the receiving Portneuf River water. Un-ionized ammonia, which can be toxic to fish, exceeded EPA's water quality standard during some days in August 1989. Macroinvertebrate sampling indicated a community of toxic-tolerant organisms and a reduction in species richness below the plant's effluent (Minshall and Robinson 1989).

Data Gaps

Most nutrient data is for the mainstem Portneuf River with only some information accumulated in the last five years. Some information is available on many of the tributaries but is, for the most part, more than ten years old.

Table 35. Water quality monitoring in the lower Poudre River, July 1992 to May 1993 (Booted Environmental, Inc. 1996). Sampling dates are approximate.

Organic Compounds

Summary Analysis

High levels of human-made organic compounds can be deleterious to human health. For example, ingestion of polychlorinated biphenyls (PCB) by humans may have an incremental increase in the risk of developing cancer over a person's lifetime (EPA 1986). PCBs can affect cold water biota beneficial use as they can be toxic to aquatic life (Great Lakes Regional Environmental Information System, internet communication). U. S. production of PCBs ceased in 1977 (GE Corporate Environmental Programs, internet communication). The threat to human health posed by these organic compounds is long term due to their persistence in the environment (Maret & Ott 1997).

Fish, especially bottom-feeders, can be good indicators of contaminants (e.g., organic compounds) in aquatic habitats. USGS sampling of fish in the Portneuf River indicated the presence of human-made organic compounds (Maret and Ott 1997; Brennan et al. 1997). Levels of PCBs exceeding National Academy of Sciences and National Academy of Engineering Health Standards have been documented in fish tissue (Utah sucker, *Catostomus ardens*) in the lower Portneuf River (Maret and Ott 1997). This site was the only site studied in the upper Snake River Basin at which organochlorine compounds were higher in the bed sediments than in fish tissue. Additional organic compounds detected included: cis-chlordane, trans-nonachlor, p,p'DDD, p,p'DDE, p,p'DDT, total chlordane, and total DDT. Usually, compounds accumulate at higher levels in the tissue of organisms than in surrounding water or sediment (known as bioaccumulation); however, that was not found to be the case in the Portneuf River for organochlorine compounds.

Pollutant Sources

Common sources of PCBs include heat transfer, hydraulic fluids, lubricants, and insecticides (Sax and Lewis 1989). Thus, sources within the Portneuf River subbasin could have agricultural, industrial, or residential origins.

Data indicating historical sources of PCBs into the Portneuf River were not found. However, Maret and Ott (1997) in their study of organochlorine compounds in the upper Snake River stated that the source of PCBs at the Portneuf River site in Pocatello "... may have urban and industrial sources...". Two Superfund sites within the city have already been documented as having been contaminated with organic compounds - volatile and semi-volatile organic compounds at the Union Pacific Railroad Sludge Pit site and PCBs at the McCarty's/Pacific Hide and Fur site.

Data Gaps

The extent of organic compound contamination of the Portneuf River streambed is unknown. Although many organic compounds (e.g., organochlorine) are no longer in use, it is not clear if there continues to be input of organic compounds from those still in use or from

historically contaminated areas. To determine if beneficial uses are presently being impaired by organochlorine compounds, more data are needed. It is recommended that water quality monitoring of the Portneuf River, its tributaries, and other sources of water into the Portneuf River (e.g., stormwater drains) include analysis for PCBs, and other organochlorine compounds such as those mentioned earlier.

Metals

Summary Analysis

The presence of metals, primarily in the vicinity of Pocatello, are a concern in the Portneuf River subbasin. Ecology and Environment (1995) listed six contaminants of concern in the Portneuf River downstream of Pocatello. The contaminants of greatest concern in the sediments of the Portneuf River and nearby springs were cadmium, fluoride, mercury, and selenium because of their potential toxicity to fish and wildlife and their tendency to bioaccumulate. Four elements were considered to be a potential concern in surface water in the same section of stream: mercury, selenium, silver, and vanadium. All four were detected at elevated levels at various springs and Portneuf River locations. Mazanowski (1992) also detected high levels of cadmium in the streambed sediments of the Portneuf River just downstream of Pocatello.

No data were reviewed that would indicate metals are impairing beneficial uses in the Portneuf River. Of the metals recognized as a concern by Ecology and Environment (1995), only cadmium was found at substantially higher elevations than background (upstream of Michaud Flats area and adjacent to Pocatello) in Portneuf River delta sediments. Despite these high levels, Ecology and Environment noted that the potential risks of sediment contamination on benthic life are expected to be minimal as the cadmium was found to be strongly bound in the sediment and not bioavailable.

Metals have also been documented in other streams within the Portneuf River subbasin. McSorley (1977) noted high concentrations of iron and manganese in Marsh Creek, probably from a non-point source. He concluded that the metals are probably not toxic due to the buffering capacity and hardness of the Marsh Creek water. Several metals have been detected in Mink Creek (Table 26). However, due to the sampling protocol used, water samples were tested for total metals, not dissolved metals for which water quality standards are written. No data exists, or is readily available, to indicate metals are affecting any beneficial use in Marsh or Mink creeks.

Pollutant Sources

All sources of metals input into the lower Portneuf River are unknown, but are most likely to be urban in origin. For example, sampling in 1979 (Division of Environment 1980) and 1994 (Candy Ross, City of Pocatello, personal communication) confirmed the presence of metals in Pocatello stormwater runoff. FMC's NPDES-permitted discharge (Industrial Waste Water ditch) contributes a small amount of metals to the Portneuf River (Bechtel Environmental, Inc. 1996).

In Mink Creek, differences in metal concentrations between the upper site, which drain predominantly Caribou National Forest, and the lower site, above which includes the forest but also substantial home development, are slight (Table 26). Thus, it appears that the sources of metals are above the Forest Service boundary and could be from natural sources.

Dead Gaps

Additional monitoring of metals as to present loading and beneficial use impairment in the Portneuf River is needed. Such monitoring should include levels of metals contributed to the river by stormwater runoff. Monitoring in Mink Creek should be done to determine if dissolved levels of, for example, copper and lead are exceeding water quality standards. Further study should also look at any current impairment of beneficial use by levels of metals found within the subbasin.

Temperature

Summary Analysis

No stream segments in the Portneuf River have temperature listed as a pollutant. However, state water quality standards for cold water biota and salmonid spawning have been exceeded in the Portneuf River, including the Downey Canal, and Marsh Creek (Table 36). Exceedances of instantaneous temperature criteria for cold water biota and, possibly, salmonid spawning have occurred in both the Portneuf River and Marsh Creek (Figures 10, 11; Appendix A). Temperature monitoring at USGS surface-water stations since late 1988 indicates that the instantaneous temperature standard for cold water biota of 71.6°F (22°C) was exceeded in the Portneuf River in Pocatello in July of 1991 and 1995. The same standard was exceeded in the Topaz area of the Portneuf River in July of 1993 and 1994. The highest temperature recorded was 76.1°F (24.5°C). The instantaneous temperature criteria for salmonid spawning was exceeded at all four USGS surface-water stations in the Portneuf River and Marsh Creek. Temperatures higher than the standard of 53.4°F (13°C) were observed in the period from May to September. As cutthroat trout spawn in April or May, depending on water temperatures, and brown trout and mountain whitefish in the October to December period (Simpson and Wallace 1982), such temperatures as seen in the Portneuf River and Marsh Creek may have no effect on spawning by salmonids.

Temperature information from Mink Creek indicates that the stream is supporting its beneficial uses. Both instantaneous and long-term monitoring from July 1997 to April 1998 showed no exceedances of the cold water biota temperature requirement (Table 26; Figures 12, 13). The salmonid spawning temperature requirement was also not exceeded during the time when salmonids in Mink Creek would most likely be spawning, i.e., outside the July to September period.

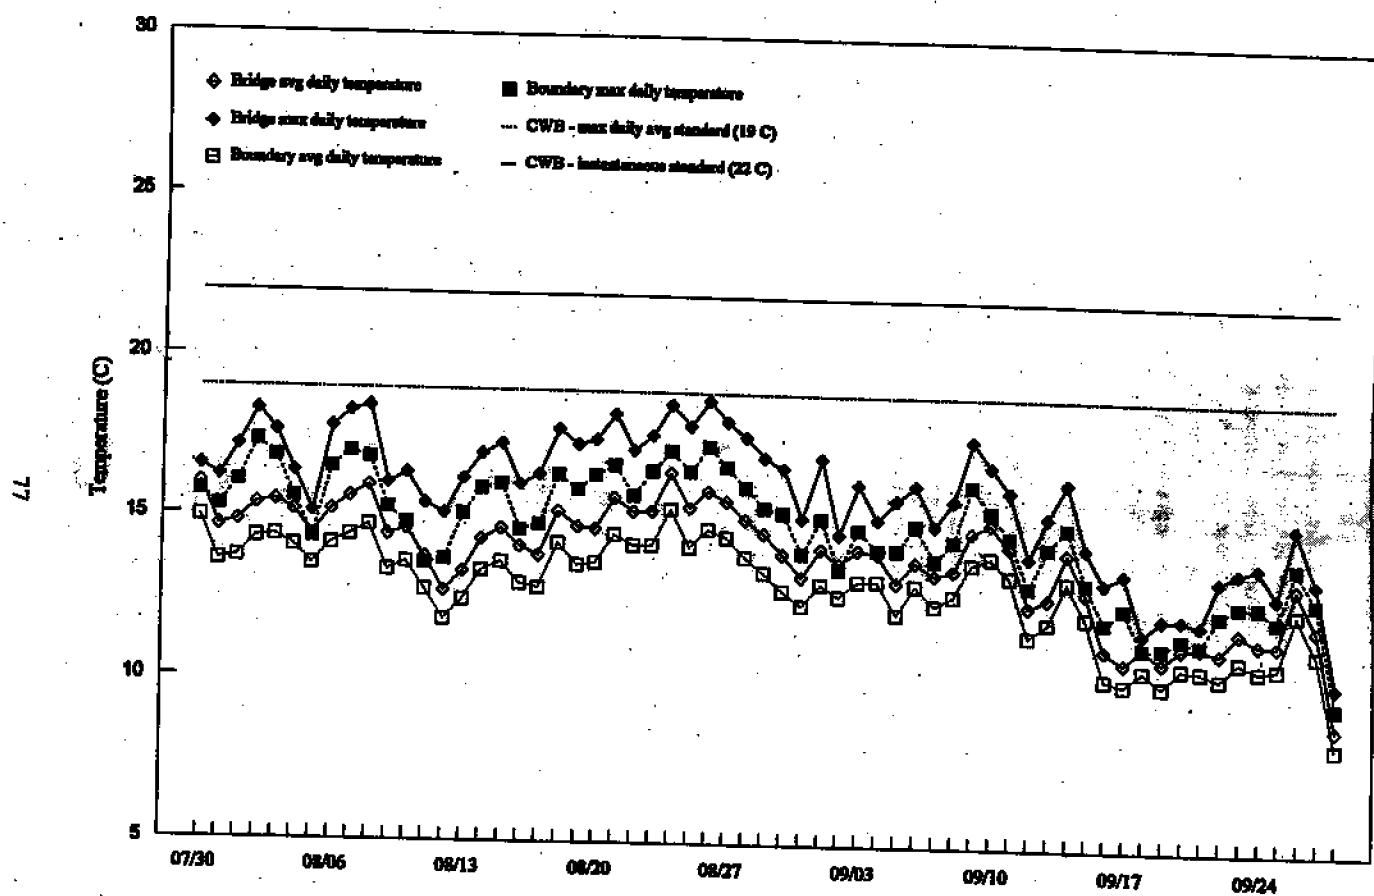

Figure 13. Temperatures recorded (every 48 minutes) by miniature temperature loggers at two sites, Forest Service boundary and Portneuf Road bridge, in the Mink Creek watershed, July to September 1997.

Pollutant Sources

Various human activities can result in elevation of stream temperatures. Habitat modification, such as removal of riparian cover which provides shade to the stream, will result in increasing stream temperatures (Platts et al. 1983, Bjornn and Reiser 1991). Other factors which can influence stream temperature are stream width and stream flow (Bartholow 1989). As stream width increases or stream flow decreases, temperatures increase (Brown 1969). Bank slumping caused by degraded streambanks can lead to increased channel width and decreased channel depth (Bauer and Burton 1993).

Human activities which have contributed to increased stream temperatures in the Portneuf River subbasin vary according to location. When channelization of streams, as has happened to sections of both the upper and lower Portneuf River, results in the permanent removal of shade-providing vegetation, solar radiation, and thus temperature, increases. Possible influences on temperatures above the Topaz and Marsh Creek gages include riparian modification by agriculture (McSorley 1977, Soil Conservation Service 1993, Portneuf Soil and Water Conservation District 1996) and irrigation withdrawals, especially above the Topaz station (McSorley 1977).

Data Gaps

Additional data should be collected to verify the extent to which temperature exceedances affect beneficial uses in the Portneuf River subbasin. This information is especially important to determine what, if any, effects instantaneous exceedances impair beneficial uses.

2.2.4 Streams Fully Supporting Beneficial Uses

Several streams within the Portneuf River subbasin are fully supporting their beneficial uses (Table 22). From information gathered as part of the Beneficial Use Reconnaissance Project, the following streams from headwater to mouth are fully supporting their beneficial uses: Gibson Jack Creek, Mink Creek, Walker Creek, Bell Marsh Creek, Goodenough Creek, Dempsey Creek, Pebble Creek, and Toponce Creek. Garden Creek from the headwaters to the Garden Creek Gap was deemed to be supporting its beneficial uses.

2.3 Summary of Past and Present Pollution Control Efforts

Several programs and projects have been undertaken since the mid-1980s in the Portneuf River subbasin to improve water quality. In addition to the efforts of private individuals and non-profit groups, projects have been undertaken by city, county, state, tribal, and federal governments under several funding programs. Probably the largest program to benefit water quality has been the State Agricultural Water Quality Program (SAWQP). Five watershed areas have benefitted from SAWQP treating about 30,000 acres (Table 37). As part of the Upper Portneuf River SAWQP project, gradient control structures were built in the Downey Canal to control stream energy and its erosive effects on the canal banks. The Natural Resources Conservation Service (NRCS) oversees three federal programs - Agricultural Conservation

Table 37. Water quality projects in the Portneuf River subbasin.

Project	Project type*	303(d) waterbodies involved	Total acre**	Amount treated**	Completion date***	Activities
Arikaree Basin	SAWQP	Marsh Creek	6,500 acres	4,083 acres	Comp	implementation of conservation tillage practices, construction of water & sediment control structures

**acres figures are approximate in some cases

***Comp = completed

Program (ACP), Food Security Act (FSA), and Conservation Reserve Program (CRP) - which have worked to improve water quality in the subbasin. The number of acres enrolled in CRP in Bannock County increased from 57,000 acres in 1988 to 63,000 acres in 1997 while CRP acres Caribou County went from 28,557 to 42,589 acres for the same time period. Sign-up of land in CRP is for ten years. Additional efforts have included fencing projects of the Friends of the Portneuf and the Idaho Department of Fish and Game. The only non-agriculture-related project has been a 319-funded engineered wetlands project by the City of Pocatello to treat a portion (~20-25%) of the city's stormwater runoff prior to its entry into the Portneuf River.

How successful most of these programs have been is unknown. Unfortunately, many of the state programs did not have an adequate monitoring plan set up to document the benefits of implementation. Drewes (1991) in his evaluation of Best Management Practices on dryland far in Marsh stated that, based on the parameters studied, there appeared to be some improvement in pollution loading, but data sets for treatment analysis were too small to determine a statistically significant improvement. Ron Davidson (NRCS, personal communication) estimated that erosion control programs of FSA, CRP, and SAWQP have combined to save almost 3 million tons of soil annually in Bannock County. There is also anecdotal evidence of improvement. Bannock County in 1994 spent \$30,000 on flood damage to roads, an 80% reduction from \$150,000 spent 10 years previous on road maintenance (letter from Bill Aller, Bannock County Highway Department, to Portneuf Soil and Water Conservation District, 23 February 1995). Much of the savings was attributed to water conservation projects implemented by agriculture.

The existing status of the river is evidence that current practices will not improve water quality to the degree that all beneficial uses will be supported in the very near future. Implementation of appropriate best management practices could, conceivably, result in the reduction in some pollutants (e.g., oil and grease) in a relatively short time (e.g., five years). However, control of sediment will require a much longer time frame.

3. PORTNEUF RIVER LOADING ANALYSIS

3.1 General

To assist in the support of beneficial uses and the improvement of water quality in the Portneuf River and its tributaries, the following recommendations are made to control the pollutants of concern into 303(d)-listed streams. The pollutants of concern include sediment, nutrients, bacteria, flow alteration, oil and grease, and dissolved oxygen.

Loading analyses are beneficial especially for those pollutants for which no numerical water quality standards exist. Many of these pollutants are addressed in narrative standards, whereby, if beneficial uses are impaired, pollutant loads are too high. A load analysis helps establish the point at which a pollutant load impairs beneficial uses. Load, and where applicable wasteload, allocations are proposed for bacteria, oil and grease, sediment, and nutrients (i.e., nitrogen and phosphorus).

Although the Portneuf River has been evaluated through many reports, little monitoring data exist at the same location in the same manner over a long period of time (e.g., 5 years). The load allocations in this report are primarily based on information from the United States Geological Survey (USGS) surface-water stations (i.e., gages) at Tyhee/Siphon, Pocatello, Marsh, and Topaz (Figure 1). Although not collected randomly and consistently, the USGS information was the only data set available which included information from the same place(s) over an extended period of time (e.g., flow information back to 1912 at Pocatello and nitrogen information back to mid-1960s). The information from USGS gaging stations (Appendices D, E) can be split into two periods. The first period began in mid-1960s ending in early 1980s. The period from about 1981 to 1986 marked a time when little water quality information was gathered. Information started flowing again in late 1980s. Calculations were made using only latter data at three upper sites as this information is more representative of present conditions due to advent of improved agricultural practices and Conservation Reserve Program (CRP) in mid-1980s. Examination of mean concentrations between the two periods confirms a general decrease in concentrations of suspended sediment, nitrates, total inorganic nitrogen, and total phosphorus (Table 38). These differences were significant for many of the parameters (Table 39).

The gaging stations will be sites at which load reductions in mass per unit time will be monitored. Reductions on tributaries will be measured by concentrations (e.g., mg/l of suspended sediment) or volume percentages (i.e., depth fines [volume of fine sediment in the streambed]).

Available data were limited in various ways. For example, USGS monitoring at their gaging stations have taken measurements of the following forms of nitrogen: nitrate, nitrate+nitrite, total nitrate, total nitrite, dissolved nitrate, dissolved nitrite, total nitrate+nitrite, dissolved nitrite+nitrate, total ammonia, dissolved ammonia, total ammonia+organic nitrogen, organic nitrogen, dissolved organic nitrogen, total Kjeldahl nitrogen, and total nitrogen. Where feasible, the different forms were lumped together such as summing dissolve nitrate plus dissolved nitrite to equal total nitrate (Appendix E). As nitrite tends to be in very low concentrations in the Portneuf River, nitrite concentrations were added to nitrate and considered all nitrate.

Table 38. Descriptive statistics summary for sediment and nutrients monitored at USGS surface-water stations.

^{AA}no early period values prevents analysis

Commonly accepted names are used for nutrients. In actuality, the following apply when discussing concentrations as expressed in milligrams per liter (mg/l): nitrate is NO₃ as N, ammonia is NH₃ as N, ortho phosphate is PO₄ as P, and total phosphorus is expressed as P.

In some cases, values for the pollutant of concern were not available. For example, the Pocatello Sewage Treatment Plant (PSTP) did not consistently keep records of nitrate in their effluent. They did, however, keep records of ammonia. A conversion factor based on one-day sample was used to calculate total inorganic nitrogen. For sediment, total suspended solids and suspended sediment were considered equivalents, although they are based on different methodology and do not usually produce the same result for a given sample.

Limitations of the data generally precludes identification of pollutant sources. Identification of sources was made wherever feasible.

3.1.1 Reasonable Assurance

The U. S. Environmental Protection Agency (EPA) requires that Total Maximum Daily Loads (TMDL) with a combination of point and nonpoint sources and with waste load allocations dependent on nonpoint source controls, provide reasonable assurance that the nonpoint source controls will be implemented and effective in achieving the load allocation (EPA 1991). If reasonable assurance that nonpoint source reductions will be achieved is not provided, the entire pollutant load will be assigned to point sources.

In the Portneuf River, a situation of point and nonpoint sources of pollutants holds true for nutrients, fecal coliform, and sediment. Nonpoint source reductions listed in the Portneuf River TMDL will be achieved through state authority within the Idaho Nonpoint Source Management Program.

Section 319 of the Federal Clean Water Act requires each state to submit to EPA a management plan for controlling pollution from nonpoint sources to waters of the state. The plan must: identify programs to achieve implementation of best management practices (BMPs); provide a schedule containing annual milestones for utilization of program implementation methods; certification by the attorney general of the state that adequate authorities exist to execute the plan for implementation of best management practices; and, include a listing of available funding sources for these programs. The current Idaho Nonpoint Source Management Program has been approved by EPA as meeting the intent of section 319 of the Clean Water Act.

As described in the Idaho Nonpoint Source Management Plan, Idaho Water Quality Standards require that if monitoring indicates water quality standards are not met due to nonpoint source impacts, even with the use of current best management practices, the practices will be evaluated and modified as necessary by the appropriate agencies in accordance with provisions of the Administrative Procedure Act (IDAPA). If necessary, injunctive or other judicial relief may be initiated against the operator of a nonpoint source activity in accordance with authority of the Director of Health and Welfare provided in Section 39-108, Idaho Code (IDAPA 16.01.02.350). Idaho Water Quality Standards list designated agencies responsible for reviewing and revising

nonpoint source BMPs based on water quality monitoring data as is generated through the state's water quality monitoring program. Designated agencies are: Department of Lands for timber harvest activities; oil and gas exploration and development, and mining activities; Soil Conservation Commission for grazing and agricultural activities; Transportation Department for public road construction; Department of Agriculture for aquaculture; and the Division of Environmental Quality for all other activities (IDAPA 16.01.02.003). Existing authorities and programs for assuring implementation of BMPs to control nonpoint sources of pollution in Idaho are as follows:

State Agricultural Water Quality Program
Wetlands Reserve Program
Environmental Quality Improvement Program
Idaho Forest Practices Act
Water Quality Certification For Dredge and Fill

Nonpoint Source 319 Grant Program
Conservation Reserve Program
Resource Conservation and Development
Agricultural Pollution Abatement Plan
Stream Channel Protection Act

The Idaho Water Quality Standards direct appointed watershed advisory groups to recommend specific actions needed to control point and nonpoint sources affecting water quality limited waterbodies. Upon approval of this TMDL by EPA Region 10, the existing Portneuf River Watershed Advisory Group, with the assistance of appropriate local, state, tribal, and federal agencies, will begin formulating specific pollution control actions for achieving water quality targets listed in the Portneuf River Total Maximum Daily Load. The Plan is scheduled to be completed within eighteen months of finalization and approval of the TMDL by EPA.

3.2 Pollutant Standards/Targets and Load Analysis

3.2.1 Flow Alteration

Target

None

Discussion

Flow alteration is a listed pollutant for the section of the Portneuf River from the downstream point of the Dowley Canal (aka Chesterfield Canal) to Lava Hot Springs (Table 19). A TMDL will not be developed for flow alteration. It is DEQ's position that flow alteration is not a pollutant per section 303(d) of the Clean Water Act nor are there water quality standards for flow. However, those water bodies for which flow alteration is listed as a pollutant often have other pollutants (e.g., sediment or temperature). Actions taken to remedy these pollutants may also address flow.

Loading Analysis

None

3.2.2 Dissolved Oxygen

Standards

Cold water biota - minimum of 6.0 mg/l except in the bottom 20% of water depth in reservoirs where depths are 35 meters or less (*Water Quality Standards and Wastewater Treatment Requirements 250.02.c.i.(1)-(3)* [Idaho Department of Health and Welfare nd])

Discussion

Only Hawkins Reservoir has dissolved oxygen listed as a pollutant of concern (Table 19). Fish kills have been reported in both summer and winter. Limited data indicated that summer dissolved oxygen levels in July of 1991 and August of 1997 met state water quality standards while levels measured in January of 1993 did not (Table 24).

Hawkins Reservoir predates the implementation of the Clean Water Act and thus is considered a pre-existing condition. It is entirely possible that, while trying to support its beneficial use as agricultural water supply, in low water years operation of the reservoir may result in low dissolved oxygen situations. Cooperation with owners on operation of the dam to maintain a minimum pool, in addition to the proposed reduction in nutrient loadings (thereby minimizing excessive plant growth), should decrease the occurrence of low dissolved oxygen. It is expected that the dissolved oxygen standard will continue to apply to Hawkins Creek below the reservoir and that operation of the reservoir will not reduce dissolved oxygen in the creek below the standards for support of cold water biota and salmonid spawning.

Loading Analysis

The data, especially winter information, are insufficient to develop a loading analysis. It is anticipated that meeting the total phosphorus target in the reservoir will reduce aquatic vegetative growth which, in turn, will reduce the chances of low dissolved oxygen conditions. At the same time, reductions in sediment, total phosphorus, and total inorganic nitrogen in Hawkins Creek should improve dissolved oxygen conditions in the reservoir.

3.2.3 Bacteria

Standard

Primary Contact Recreation - 1 May to 30 September (Water Quality Standards and Wastewater Treatment Requirements 250.01.a.i.-iii. [Idaho Department of Health and Welfare nda])

500 colonies/100 ml at any time, or

200 colonies/100 ml in more than 10% of the total samples taken over a 30-day period, or

Geometric mean of 50 colonies/100 ml or greater based on a minimum of 5 samples over a 30-day period

Secondary Contact Recreation (Water Quality Standards and Wastewater Treatment Requirements 250.01.b.i.-iii. [Idaho Department of Health and Welfare nda])

800 colonies/100 ml at any time, or

400 colonies/100 ml in more than 10% of the total samples taken over a 30-day period, or

Geometric mean of 200 colonies/100 ml or greater based on a minimum of 5 samples over a 30-day period

Discussion

Only the mainstem Portneuf River has bacteria listed as a pollutant of concern (Table 19). However, many tributaries within the subbasin have exceeded state water quality standards for fecal coliform, for example, Pocatello and Mink creeks, and North Fork of Pebble Creek in 1998 (Table 40). Origins of fecal coliform include livestock, wildlife, and human. Stormwater runoff from Pocatello has also been mentioned as a source of fecal coliform into the Portneuf River (Hancock and Bybee 1978).

All streams within the Portneuf River subbasin must at least meet secondary contact recreation standards for fecal coliform. Streams which have primary contact recreation as a beneficial use must meet a more strict fecal coliform requirement for primary contact recreation from 1 May to 30 September.

Additional data are needed to identify specific sources of bacteria into the Portneuf River. For example, regular monitoring of tributaries at the mouth would indicate those areas which are sources of bacteria input. The most extensive data are from 1 May to 30 September - the period in which primary contact recreation is considered to occur. Regular sampling to document exceedances of secondary contact recreation standards is also essential.

Table 40. Exceedances of state water quality standards for fecal coliform in the Portneuf River subbasin since 1990.

*P=primary contact recreation, S=secondary contact recreation.

Loading Analysis

The load analysis is based on the geometric mean (geomean) as this was the criterion most often violated and the geomean represents a chronic water quality problem compared to instantaneous measurements. Secondary contact recreation standards were not exceeded in the Portneuf River based on data used in this analysis (Appendix C). The geometric mean standard for primary contact recreation is 50 colonies/100 ml.

Data sufficient to develop a loading analysis in the Portneuf River from Chesterfield Reservoir to American Falls Reservoir varies according to location. The most recent data available are from sampling events in August and September 1998 in the lower Portneuf River through Pocatello. In the reach of river from the upstream end of the City of Pocatello (Rainey Park) to Lava Hot Springs, data from 1990 to 1996 were used. No recent (since 1990) information on bacteria in the Portneuf River from Pebble Creek to Lava Hot Springs was available, hence no load was calculated for this stretch of stream. Above Pebble Creek to Chesterfield Reservoir, fecal coliform sampling was done from 1995 to 1997.

Based on 1998 data, with some support from other fecal coliform sampling since 1989, a coarse loading analysis was developed for the section of Portneuf River through Pocatello to Tyhee gage. The loading analysis is for 1 May to 30 September for primary contact recreation as outlined in the State of Idaho Water Quality Standards (Idaho Department of Health and Welfare nda). State water quality standards for fecal coliform for primary contact recreation waters were considered the loading, or assimilative, capacity of the Portneuf River.

It appears that most of the fecal coliform input occurs downstream of the Pocatello USGS gage site (Table 41). One sample taken at Rainey Park, at the upstream end of the river through the City of Pocatello, in September 1998 showed a fecal coliform count of 82 colonies/100 ml. Earlier data (e.g., July 1991) documented over 100 colonies/100 ml above Rainey Park. The 1998 data indicate that Mink Creek is a source of input into the section of the Portneuf River above Rainey Park. The extent of contribution from Mink Creek to the river is unknown. However, for this analysis a fecal coliform load of 82 colonies/100 ml at Rainey Park was used. No information was collected in 1998 between Rainey Park and the Pocatello gage site. From instantaneous sampling at the gage site from 1991 to 1996, it appears that the load of fecal coliform increases through this concrete channelized reach indicating a source of input (e.g., tributaries, stormwater). In 1998, the load of fecal coliform between the Pocatello gage and Pocatello Creek was a geometric mean of 238 colonies/100 ml. Pocatello Creek with a geometric mean of 442 colonies/100 ml in 1998 appears to be a serious source of fecal coliform into the Portneuf River. Discharge measurements were not taken during the sampling for bacteria so dilution effect of Portneuf River water on heavily laden fecal coliform water from Pocatello Creek is unknown. As the geometric mean below Pocatello Creek to Kraft Road bridge (about 0.5 miles) was only 193 colonies/100 ml some dilution may be occurring. However, the mean, based on only two samples, may be artificially low. Two other samples were unusable as number of colonies were not countable or too numerous to count (Appendix C). Once the river reaches the interstate, 2.5 miles downstream of Kraft Road bridge, numerous springs add to the river flow potentially diluting fecal coliform concentrations. Data from Tyhee gage site from 1990 to 1994

Table 41. *when only 1 sample was collected, the value is an instantaneous value; when 2 or more samples taken during the month, the value is a geometric mean.

Geometric means were calculated only on a monthly basis not a 30-day period.

**geomean calculated from a pool of all data for 1998 by location. No geomean was estimated at Rainey Park because only one sample was taken.

show relatively low levels of fecal coliform although a 1989 sample indicates that fecal coliform may occasionally be high.

Although six years of data were available, only data from 1990, 1991, 1993, and 1996 were employed in the load analysis for fecal coliform in the Portneuf River reach from Lava Hot Springs to about the upstream edge of the City of Pocatello. In the other two years, less than four samples were collected and thus were not used in the analysis (Table 42). All samples from May to September, the period in which primary contact recreation standard applies, were pooled to calculate a geometric mean. The average geometric mean for the four years was 136 colonies/100 ml.

Sampling in the Downey Canal reach (Pebble Creek to Chesterfield Reservoir) of the Portneuf River occurred at six sites from 1995 to 1997. Rather than treat each site individually all six sites were pooled to estimate fecal coliform concentration in the Downey Canal reach although the downstream site, P6, was below the confluence of the canal with the old river channel. Geometric means for all 30-day periods from May to September for three years ranged from 19 to 141 (Appendix C). The average geometric mean for three years was 54 colonies/100 ml.

Load reductions are based strictly on percentage reduction due to lack of more extensive data. Although all numbers presented do not represent a geometric mean based on at least five samples, they were treated as such. Reduction in loads were determined by subtraction of estimated load from the geometric mean standard for primary contact recreation. An additional 10% was added on each load as a margin of safety. These reductions are proposed for 1 May to 30 September.

The greatest reduction in fecal coliform input is in the lower Portneuf River. Proposed load reductions range from 17% in the Downey Canal reach to 80% for the reach of river between the Pocatello gage to Pocatello Creek (Table 43).

The loads were not apportioned by source. Data were considered either non-existent (i.e., contribution by livestock, wildlife, or human nonpoint sources), incomplete (i.e., not all tributaries were monitored), or too old (i.e., collected over 10 years ago) to reflect current conditions in the Portneuf River. Historic contributors of fecal coliform into the Portneuf River, include: Jenkins Canyon, Sorrell Canyon, Jackson Creek, Indian Creek, and South Fork Pocatello Creek (Drewes 1987); Eighteenmile Creek, Twentyfournmile Creek, and Toponce Creek (Hoover 1985); and Marsh Creek (Frenzel and Jones 1985, Perry et al. 1977, and McSorley 1977).

No wasteload allocations are recommended. Discharge Monitoring Reports (DMRs) for FMC or Batise Springs Hatchery do not include any monitoring of fecal coliform. DMRs from the cities of Pocatello, Inkom, Lava Hot Springs do not indicate that these dischargers are major contributors of fecal coliform into the Portneuf River. Since November of 1997, data from the Pocatello STP indicate the highest average fecal coliform count was 42 colonies/100 ml while the maximum recorded was 90 colonies/100 ml. At low flow, the Pocatello STP discharge represents about 6% of flow in the Portneuf River at its effluent discharge point (Brock 1989). The highest average fecal coliform count documented on DMRs from the Inkom STP since November 1997

*may not represent a geometric mean of at least 5 samples collected within a 30-day period; see Table 41 and Appendix C

was 13 colonies/100 ml. For the same period, Lava Hot Springs STP reported an average high of 22 colonies/100 ml. Effluent from Inkom and Lava Hot Springs sewage treatment plants accounts for about 0.05% of flow in the Portneuf River at point of discharge. Based on low numbers of fecal coliform in the three sewage treatment plant effluents and low percentage of overall flow in the river these discharges represent no wasteloads for fecal coliform are proposed.

Margin of Safety

Load reductions for the Portneuf River were determined by subtracting the estimated load from the geometric mean standard for primary contact recreation. To allow for a margin of safety, an additional 10% was added on to each load (see Table 43).

Data Gaps

The load reductions are not apportioned by source because information was deemed either too old or sampling was instantaneous only. More information is needed as to frequency and timing of exceedances, input sources, etc., before a more complete loading analysis can be attempted.

3.2.4 Oil and Grease

Target

oil and grease content not to exceed 5 mg/l

Discussion

The lower Portneuf River in vicinity of the City of Pocatello is the only stream segment that has oil and grease listed as a pollutant of concern. There was no information found as to extent to which oil and grease are affecting beneficial uses in the Portneuf River. In addition, no data were seen which would indicate amounts of oil and grease discharged into the Portneuf River. Oil and grease into the Portneuf River can come from both agricultural and urban inputs, however, Pocatello and Chubbuck are most likely the source of loads into this listed segment of stream.

To estimate the oil and grease contributed to the Portneuf River by Chubbuck and Pocatello, land use information from the cities (Surface and Wessel 1995) was entered into a model based on stormwater pollutant information from urban areas throughout the United States (Table 44). The model estimated the annual total stormwater runoff of oil and grease at 75,948 pounds (38 tons).

To determine if beneficial uses are presently being impaired by oil and grease, more data are needed. It is recommended that water quality monitoring of the Portneuf River, its tributaries,

Table 44. Estimated total suspended solids and oil and grease loads from stormwater runoff from the Pocatello-Chubbuck urban area (land use information from Surface and Wessel 1995; modeling done by Todd McGuire, Division of Environmental Quality).

and other sources of water into the Portneuf River (e.g., stormwater drains) include analysis for oil and grease (or a derivative such as total petroleum hydrocarbons).

Load Analysis

Until more information is gathered as to whether oil and grease are affecting beneficial uses in the Portneuf River, a target concentration of oil and grease content not to exceed 5 mg/l is recommended. A limited search for water quality standards or targets for oil and greases yielded a water quality standard of 10 mg/l from the State of Wyoming (Department of Environmental Quality, State of Wyoming, internet communication). To allow for a margin of safety, the Wyoming standard was decreased by half to account for lack of data on effects of oil and grease on beneficial uses. No targets or standards for oil and grease above which an aesthetic beneficial use is impaired were unearthed.

The maximum allowable load based on a target concentration of 5 mg/l and an estimated annual flow below the area of impact of 168,003 cfs (Table 45) is about 2,268 tons per year:

$$5 \text{ mg/l} \times 168,003 \text{ cfs} \times 0.0027 \text{ [conversion factor to tons/yr]} = 2,268 \text{ tons/year.}$$

No information was available to estimate the load of oil and grease from other nonpoint sources and there was no indication that any point source was contributing to the load of oil and grease in the Portneuf River.

The estimated current load of 38 tons/yr is substantially less than the allowable load of 2,268 tons/yr. However, at times (e.g., an intense summer rainstorm following weeks of no rain) the estimated load may actually approach the target load. Assuming that the estimated annual load of 38 tons of oil and grease from stormwater runoff is evenly distributed throughout the year, then a three week dry spell, not unusual for July or August, would mean an accumulation of 2.2 tons of oil and grease (3 weeks + 52 weeks x 38 tons) in the city. A summer storm occurred on 10 July 1998 that dropped 0.23 inches of rain at the National Weather Service (NWS) monitoring station about eight miles west of the City of Pocatello (National Weather Service, internet communication). Such a storm would produce about 11.5 million cubic feet of stormwater runoff assuming similar precipitation patterns between the monitoring station and the Pocatello-Chubbuck urban area. This would create a spike in loading to the Portneuf River as well as an increase in load capacity due to increased stream flow.

Flow information at the Pocatello USGS surface-water station from 8-15 September and 29 September-6 October 1998 (USGS, internet communication) was examined to determine an empirical relationship between stream flow and short-term precipitation. Two storm events, 10 and 30 September (recordings of 0.35 and 0.09 inches of precipitation at the NWS monitoring station, respectively [National Weather Service, internet communication]) each resulted in an increase in flow at the Pocatello USGS surface-water station of about 100 cfs. Visual inspection of the two events indicated about 85% of the increase in flow occurred in about 4.5 hours.

Table 45. Estimated monthly load and target load of oil and grease in the Portland River.

	Month												
	January	February	March	April	May	June	July	August	September	October	November	December	Total
Mean flow (cf)	501	561	683	659	552	287	194	283	338	457	507	506	5,527
Total monthly flow	15,531	15,848	21,142	19,770	17,112	8,610	6,014	8,773	10,140	14,167	15,210	15,686	168,003
Target load (tons)	210	214	285	267	231	116	81	118	137	191	205	212	2,268
Estimated load (kms)**	3	3	3	3	3	3	3	3	3	3	3	3	38

*USGS Tybee surface-water station, Water Years 1985-1994

**total load of 38 tons of oil and grease from stormwater runoff equally divided between the 12 months

Using the above empirical relationship, then the stormwater runoff from a storm producing 0.23 inches would contribute about 600 cfs to the river both above and below the Pocatello gage ($[11,571,013 \text{ ft}^3 \text{ of stormwater runoff} \times 0.85] + [4.5 \text{ hours} \times 3600 \text{ seconds/hour}] = 607 \text{ cfs}$). Adding this flow to a late summer low flow at the Tyhee USGS surface-water station of 136 cfs (July 1990 [USGS water resources data]) yields a total flow of 743 cfs. A target load for oil and grease at this flow is 1.9 tons/4.5 hours ($743 \text{ cfs} \times 5 \text{ mg/l} \times 0.000112$ [conversion factor to tons/hr] $\times 4.5 \text{ hours} = 1.87 \text{ tons}/4.5 \text{ hours}$). Assuming that 90% of the 2.2 tons of accumulated oil and grease is delivered to the river within the 4.5 hour period, then the input of 2.0 tons of oil and grease would exceed the 4.5 hour limit of 1.9 tons at a target of 5 mg/l. Assuming runoff from the storm entered the Portneuf River within 24 hours, the 1.9 ton load of oil and grease would not exceed the daily target of 3.6 tons ($11,571,013 \text{ ft}^3 \text{ of stormwater runoff} + [24 \text{ hours} \times 3600 \text{ seconds/hour}] = 134 \text{ cfs}$; $[134 \text{ cfs} + 136 \text{ cfs}] \times 5 \text{ mg/l} \times 0.0027 = 3.6 \text{ tons}$).

The loading analysis indicates that conditions could be such that the target load capacity could be exceeded on a short term basis. Until such time that data indicate otherwise, it is recommended that there be no increase in the present input of oil and grease into the Portneuf River.

Margin of Safety

The input of oil and grease into the Portneuf River and its effect on water quality is unknown. The Wyoming standard was decreased by half, from 10 mg/l to 5 mg/l, as a margin of safety to account for the lack of data on the effects of oil and grease on beneficial uses.

Data Gaps

Numerous assumptions were part of the foregoing scenario - an indication that much more information is needed on oil and grease in the Portneuf River. In addition, there was no accounting for effect of the soon-to-be-online engineered wetlands for treating storm water runoff in the City of Pocatello. Data should be collected to determine if there is a load of oil and grease into the river, and what, if any, impact such a load is having on beneficial uses.

3.2.5 Sediment

Standard

Sediment - shall not exceed quantities specified in Section 250, or, in the absence of specific sediment criteria, quantities which impair designated beneficial uses. Determinations of impairment shall be based on water quality monitoring and surveillance and the information utilized as described in Subsection 350.02.b (*Water Quality Standards and Wastewater Treatment Requirements 200.08*, [Idaho Department of Health and Welfare N.A.])

Target

Suspended Sediment

High flow - not to exceed a 14-day average of greater than 80 mg/l

Low flow - not to exceed a 28-day average of greater than 50 mg/l

Depth Fines

Subsurface streambed sediment less than 6.25 mm not to exceed a 5-year mean of greater than 25% by volume in riffles

Subsurface streambed sediment less than 0.85 mm not to exceed a 5-year mean of greater than 10% by volume in streams with salmonid spawning as a beneficial use in riffles

Discussion

All streams on the 303(d) list in the Portneuf River have sediment listed as a pollutant of concern (Table 19). Major sources of sediment include agricultural, both farming and grazing, and urban activities (Hancock and Bybee 1978; Hoover 1985; Ozburn and Modersitzki 1986; Soil Conservation Service 1993). Streambanks have also been identified as substantial sources of sediment in the Portneuf River (Heimer and Ratzlaff 1987; Portneuf Soil and Water Conservation District 1996).

Sediment loads within the Portneuf River subbasin have been estimated by various authors (Table 46). From 1965 to 1977, the estimated annual sediment load in the Portneuf River decreased from 2.6 million tons to about 1 million tons. During the same period, estimated sediment loads decreased by two-thirds in Marsh Creek. The reason for this estimated decrease in sediment loads is unknown.

Present loads, along with an estimate of natural sediment input, were calculated based on sediment yield from various types of land uses above the Pocatello, Marsh Creek, and Topaz USGS surface-water stations (Tables 47, 48, 49, 50; Appendix D). About 77,500 acres in the southeast area of the subbasin, south and east of Bancroft, were not used in the calculations as it appears that any drainage/ runoff from this area does not reach any major tributary or the Portneuf River. Sediment input from streambanks was calculated on a tons/mile segregated by stream size rather than riparian area. Sediment loads ranged from about 125,000 tons for the area above Topaz to 400,000 tons for the subbasin above Pocatello. These loads seem reasonable compared to previous estimates based on improvement in land use practices on agricultural land in the subbasin and transfer of cropland into the Conservation Reserve Program.

Sediment delivery curves were used to estimate suspended sediment loads above three gage sites (Figure 14). Loads were calculated from daily flow information at three gaging stations using a simple linear regression model (Appendix F). Daily loads were summed to get the total annual load from 1955 (first full year of operation for Marsh Creek gage) to 1995 (Appendix D). Loads based on target concentrations were made by multiplying the appropriate concentration (Table 51) by average daily flow per month by number of days in the month. Loads by month

**based on data since 1983

were summed to get the total annual load (Appendix D). Average annual loads for all estimates were derived from total loads from years 1955 to 1995.

In-stream suspended sediment loads as estimated at the gage sites were substantially less than those estimates from land use sediment yield (Tables 47, 48, 49, 52). Some difference might be expected at Pocatello and Marsh Creek as the correlation index (R^2 - a measurement of the intensity of association between two variables) are 0.27 and 0.34, respectively. However, flow and sediment have a much closer relationship at Topaz where the R^2 value is 0.80. First it should be pointed out that sediment yield was delivery of sediment to a stream. Retention of sediment in adjacent streams which does not reach the mainstem would explain some of the difference between sediment yield and suspended sediment as measured at gage sites on Portneuf River or Marsh Creek. Another possible reason for difference is that the regression equations may substantially underestimate the amount of sediment moving during spring runoff. Sampling at the sites was limited during spring runoff. Finally, sediment which moves along the streambed (bedload) rather than suspended in the water column would not be included in the estimates of suspended sediment loads. No data have been reviewed that gave any values for bedload in the Portneuf River. Information on size of suspended sediment (Appendix D) indicates that particle size is primarily less than 0.062 mm (88% - overall median from the four gaging stations, 1980-1995) possibly indicating larger particles are moving as bedload. Sediment targets and load reductions were based on suspended sediment with the assumption that decreases in suspended sediment would mean concurrent reductions in other forms of sediment (e.g., bedload).

Load Analysis

Suspended Sediment

Targets to establish the load reduction were based on effects of sediment in the water column (suspended sediment) and when it settles out (depth fines). Conditions less than or equal to the recommended targets will result in improving support of beneficial uses within the subbasin.

Site-specific targets for suspended sediment in the Portneuf River were not attempted. Information was reviewed on site-specific levels of suspended sediment or total suspended solids needed to support beneficial uses in the Portneuf River. Loading, or assimilative, capacity was not estimated because of a paucity of data. For purposes of the loading analysis, assimilative capacity was considered to be equal to the target load.

The targets for suspended sediment are: 1) outside the spring runoff period not to exceed a 28-day average of 50 mg/l, and 2) during spring runoff not to exceed a 14-day average of 80 mg/l. The European Inland Fisheries Advisory Commission (EIFAC 1964) in their review of suspended solids in relation to fisheries concluded that concentrations less than 25 ppm have no harmful effect on fisheries; concentrations of 25-80 ppm will have some effect but it is possible to maintain good to moderate fisheries; concentrations of 80-400 ppm are unlikely to support good fisheries; and, concentrations greater than 400 ppm will at best result in poor fisheries.

Table 52. Estimated reductions in load (tons/year) for suspended sediment at USGS surface-water stations.

Site	Natural load*	Present suspended sediment load**	Confidence interval***	Target load^	Load reduction^^	Percent reduction from present load
Pocatello	12,410	34,346	± 16,399	19,263	35,083	65%
Marsh Creek	3,135	16,309	± 4,467	5,372	10,937	67%

*See Table 50

**average annual load from 1955 to 1995, except 1986-1993 at Tyhee. Annual load derived by summing daily suspended sediment loads estimated from flow:suspended sediment linear regression models of data collected at the gage sites since 1990 (Pocatello, Marsh Creek) or 1993 (Topaz); see Figure 14.

***95% confidence interval for present suspended sediment load estimate

^average annual load from 1955 to 1995, except 1986-1993 at Tyhee. Annual load derived from the sum of the monthly loads calculated by multiplying the appropriate target concentration by the average flow per month by the number of days per month.

^^difference between present and target loads

Newcombe and MacDonald (1991) argued that duration of the event must also be considered in addition to concentration of suspended sediment.

Evaluating recommended targets using models suggested by Newcombe and Jensen (1996) showed mixed results. The recommended targets fall below the lethal and paralethal range as determined by concentration-duration tables for juvenile and adult salmon (Models 1-3; Table 53). Both targets at the recommended duration of either 14 days or 28 days would fall within the lethal and paralethal range for eggs and larvae of salmonids and non-salmonids and for adult freshwater nonsalmonids based on Newcombe and Jensen's Models 4 and 6, respectively. The durations which would have to be met to fall "below" the lethal/paralethal range (sublethal) are about 1 day at both 50 and 80 mg/l for eggs and larvae of salmonids and non-salmonids (Table 54). For adult freshwater nonsalmonids, the lethal range duration thresholds are less than 5 days at 50 mg/l and 4 days at 80 mg/l. It is unknown whether at certain times of the year (e.g., spring runoff or intense summer rainstorms) the Portneuf River may have naturally exceeded these concentrations of 50 and 80 mg/l for durations of greater than 5 days.

Targets for the Portneuf River are congruent with other "local" standards and targets. Nevada has a state standard of 25 and 80 mg/l depending on the water body classification. Targets have been set at 56 mg/l in tributaries and return drains in the Yakima River in Washington (Joy and Patterson 1997); 35 mg/l for smaller streams, 90 mg/l for larger streams in the Bear River in Utah (Ecosystem Research Institute 1995); and 50 mg/l and 80 mg/l for the lower Boise River (Division of Environmental Quality 1998).

The suspended sediment targets are recommended despite modeling which indicates that the targets may have lethal or paralethal effects on the fish community in the Portneuf River. Considering that good to moderate fisheries can be maintained at these target concentrations (EIFAC 1964) and that natural conditions may have exceeded sublethal durations at target concentrations, the decision was made to recommend the two targets. The targets will be subject to change based on information indicating the natural concentrations of suspended sediment and the duration exposure on fish or information indicating proposed targets do not support beneficial uses.

Effectiveness monitoring sites were set at Pocatello, Marsh Creek, and Topaz USGS surface-water stations. Tyhee was not chosen because the area between Tyhee and Pocatello gages is an area of deposition of sediment (compare mean concentrations and flow:suspended sediment regression equation since 1989 in Table 38 and Appendix F, respectively; Bechtel Environmental, Inc. 1994) and, therefore, would be a less accurate measure of sediment load than the Pocatello gage site.

Total load reductions of suspended sediment are presented in Table 52. The present suspended load is the average annual load from 1955 to 1995 based upon the flow:suspended sediment regression equation. Target load capacities were also the average annual load for the same time period calculated from the monthly load summed on an annual basis. The difference between the present load and target load represents the load reduction. Load reductions ranged from 53% at Topaz to 67% at Marsh Creek.

Table 53. Severity of ill effect (SEV) from target loads of suspended sediment for high flows and low flows in the Portage River subbasin (based on Newcombe and Jensen 1996). Ranges of severity of ill effect are nil effect (SEV=0), behavioral effects (SEV=1-3), sublethal effects (SEV=4-8), and lethal and paralethal effects (SEV=9-14). Target loads at high flow are not to exceed a mean of 20 mg/l over a 14-day period. Target loads at low flow are not to exceed a mean of 50 mg/l over a 28-day period.

	Model*				
	1	2	3	4	6
High flow	8	8	8	11	9
Low flow	8	8	8	12	10

*models 1-3 are for juvenile and/or adult salmonids in streams where particle size ranges from fine (predominantly < 75 µm) to coarse (75-250 µm). Model 4 is for eggs and larvae of salmonids and nonsalmonids and fine particle sizes. Model 6 is for adult freshwater nonsalmonids and fine particle sizes.

Table 54. Duration of exposure (days) at suspended sediment concentrations of 50 and 80 mg/l which results in a severity of ill effect below the lethal and paralethal class (SEV<=8) for eggs and larvae of salmonids and nonsalmonids and adult freshwater nonsalmonids (based on Newcombe and Jensen 1996).

	Model*	
	4	6
High flow	0.92	3.60
Low flow	1.05	4.34

*model 4 is for eggs and larvae of salmonids and nonsalmonids and fine particle sizes. Model 6 is for adult freshwater nonsalmonids and fine particle sizes.

Loads of suspended sediment were apportioned by source based on estimated percentage of sediment yield by land use (Tables 47, 48, 49). The burden of load reduction is on agriculture, primarily dryland agriculture (Table 55). Other major sources of sediment into the Portneuf River subbasin streams include rangeland and the streams themselves, either through streambank erosion or scouring of streambed sediment during high flow events. Please note that natural loads were considered part of the target loads, not in addition to the target loads.

As flow information is limited on the tributaries, no load reductions were estimated. However, targets will remain the same as at the gaging stations. For streams above Topaz station, the high flow target of suspended sediment not to exceed 80 mg/l will be applicable from April to June and the low flow target of 50 mg/l from July to March. For all other streams (e.g., Portneuf River below Pocatello gage site), the high and low flow targets will be applicable from February to March and April to January, respectively (Table 51).

Discharge of total suspended solids from four NPDES-permitted dischargers for which information is available has been less than the target suspended sediment concentrations (Table 56). The permit requirements for total suspended solids at Pocatello and Lava Hot Springs sewage treatment plants are a 7-day average not to exceed 45 mg/l and a 30-day average not to exceed 30 mg/l. The two STPs have averaged 12 and 7 mg/l of TSS, respectively, for the last full year of available data. The Batise Springs Hatchery's permit for total suspended solids requires the daily average not to exceed 5 mg/l with the daily maximum no greater than 15 mg/l. The permit for Inkomin STP limits total suspended solids in effluent to maximum 7-day and 30-day averages of 105 and 70 mg/l, respectively; average TSS concentration from November 1997 to October 1998 was 22 mg/l. Although permit limits exceed the recommended target concentration, STP limitations are for total suspended solids not suspended sediment. At present input levels, there is no need for a reductions in wasteloads for the three STPs and Batise Springs Hatchery. Therefore, no wasteload reduction is proposed, but it is recommended and consistent with state policy that current input of total suspended solids not increase.

Margin of Safety

The chosen targets allow for a margin of safety well within the range of suspended sediment which is required to maintain good to moderate fisheries. The targets, which are seasonally based, result in an annual average of 62 to 64 mg/l (Table 51), well within the range of 25 to 80 mg/l required to maintain good to moderate fisheries (EIFAC 1964).

As an additional margin of safety, the average suspended sediment load from 1955 to 1995 was used in the load analysis. The average annual loads represented the 69th, 67th, and 68th percentile of all loads estimated during the time period at the Pocatello, Marsh Creek, and Topaz surface-water stations. In other words, the average annual loads at all three gage sites were in about the upper 30% of all the estimated loads. Therefore, total reductions in suspended sediment load are greater using the annual average than had the median annual load been used.

The load allocation of total suspended solids from Pocatello-Chubbuck storm water runoff also included a margin of safety. The estimated target load capacity was reduced by 5%.

Data Gaps

Additional information would help to improve the TMDL in future years. For example, sediment input from canals and ditches in the upper Portneuf River was estimated but no information was located on the contribution from canals and ditches in Marsh Creek or the lower Portneuf River. Little information is available on urban input of sediment in the subbasin such as from construction sites or the fraction of suspended sediment in the total suspended solids input from sewage treatment plants. The effect of increased snowpack and resultant runoff from cloud seeding is unknown. Past effects of sediment input from drawdown of Chesterfield Reservoir are difficult to quantify. At a minimum, regular monitoring at the mouth of tributaries, canals/ditches, storm water drains, etc., would help quantify the contribution these sources make to sediment loading in the Portneuf River. Additional monitoring during spring runoff might narrow down differences in sediment loading based on land use and concentrations of suspended sediment at the surface-water stations.

Depth Fines

No loads for volume of streambed subsurface sediment were estimated for lack of information. In addition, no information was available to establish a linkage between reduction in suspended sediment loads and corresponding reductions in streambed subsurface sediment. As previously stated, it is assumed that in setting a load reduction of suspended sediment, there is an expected concomitant reduction in all sediment to streams in the Portneuf River subbasin. To ensure that such a decrease is occurring, targets are set for subsurface streambed sediment (depth fines) less than 6.25 mm not to exceed a 5-year mean of 25% by volume, and depth fines less than 0.85 mm not to exceed a 5-year mean of 10% by volume in all streams supporting, or designated to support, salmonid spawning in the Portneuf River subbasin. Both targets are recommended for riffle areas only, primarily those sections conducive to salmonid spawning.

Numerous agencies have set targets for depth fines to support primarily salmonid fisheries. The Salmon and Challis National Forest bases subsurface sediment standards on watershed geology (Betsy Rieffenberger, Salmon and Challis National Forest, personal communication). In granitic, volcanic, and sedimentary drainages, streams in good, fair, and poor condition will have < 25%, 25-30%, and > 30% fines, respectively. Montana recognized a subsurface sediment standard in their Deep Creek TMDL of 30% fines < 6.35 mm (Endicott and McMahon 1996). The Idaho Division of Environmental Quality (Division of Environmental Quality 1991) set two targets for the South Fork Salmon River: 1) for those streams with subsurface sediment less than 27%, maintain the existing sediment volume level; and, 2) for streams that exceed the 27% threshold, reduce subsurface sediment to a 5-year mean not to exceed 27% with no individual year to exceed 29%. Based on Burton et al. (1990) work in southern Idaho (e.g., Rock Creek near Twin Falls), a 27% target for subsurface sediment would be applicable to the Portneuf River. To include a margin of safety, the target was set at 25% for depth fines.

Several reports have proposed that smaller sediment (< 0.85 mm) is especially harmful to salmonids during the incubation and emergence period (Hall 1986; Reiser and White 1988). To support salmonid spawning, the depth fines < 0.85 mm target is recommended.

Due to variability of sediment transport in the Portneuf River, targets are set over a 5-year time period. This recommendation is similar to the TMDL established in the South Fork of the Salmon River (Division of Environmental Quality 1991).

Margin of Safety

As mentioned above, a 27% target for subsurface sediment less than 6.25 mm by volume would be applicable (Burton et al. 1990). The target was set at 25% to allow a margin of safety.

Data Gaps

The link between suspended sediment reductions and reduction in depth fines is unknown. Monitoring of reductions in both parameters may help deduce such a relationship.

3.2.6 Nutrients

Standard

Un-ionized ammonia - not to exceed criteria for cold water biota and salmonid spawning
(in streams with salmonid spawning as a designated or existing beneficial use)
(Water Quality Standards and Wastewater Treatment Requirements
250.02.c.iii [Idaho Department of Health and Welfare N.A.]

Excess nutrients - surface waters of the state shall be free from excess nutrients
that can cause visible slime growths or other nuisance aquatic growths impairing
designated beneficial uses (*Water Quality Standards and Wastewater Treatment*
Requirements 200.06 [Idaho Department of Health and Welfare N.A.])

Target

Nitrogen not to exceed 0.3 mg/l of nitrogen as total inorganic nitrogen

Phosphorus

Rivers - not to exceed 0.075 mg/l of phosphorus as total phosphorus

Hawkins Reservoir - not to exceed 0.025 mg/l of phosphorus as total phosphorus

Discussion

About half of the water bodies on the 303(d) list in the Portneuf River subbasin have
nutrients identified as a pollutant, including the entire Portneuf River from Chesterfield Reservoir
to American Falls Reservoir (Table 19). Major inputs of nutrients above the City of Pocatello

include agriculture, both cropland and livestock (McSorley 1977; Hoover 1985; Drewes 1987; Rupert 1996). Point source pollution in the upper Portneuf River is insignificant in comparison with nonpoint source pollution (McSorley 1977). Within and below the urban areas of Pocatello and Chubbuck, major nonpoint sources of nutrients are of urban (Perry and Clark 1990, Campbell et al. 1992) and agricultural origins (Drewes 1987; Rupert 1996). Point sources of nutrients in the lower Portneuf include springs (Perry et al. 1977; Perry and Clark 1990) and the City of Pocatello's sewage treatment plant (Perry et al. 1977; Brock 1989).

Estimates of nutrient loading in the Portneuf River subbasin have been limited (Table 57). Hoover (1985) estimated annual nitrate, total phosphorus, and ortho phosphate loads from the Portneuf River drainage above Pebble Creek at 94.4, 8.4, and 2.9 tons/yr, respectively. Estimates made by Riedel (1998) for the same area seem to indicate that nutrient loadings, especially for nitrogen, have diminished in the last 20 years.

Targets are recommended for both nitrogen and phosphorus. Minshall and Andrews (1973) reported that at certain times of the year nitrogen in the form of nitrate is limiting. Generally, the ratio of nitrogen to phosphorus within phytoplankton is somewhere in the range of 10:1 to 17:1 (Mackenthun 1973). A rudimentary look at the ratio of total inorganic nitrogen (TIN) to total ortho phosphorus (a form of phosphorus most readily available for nutrient uptake than total phosphorus), indicates that, based on ratio of means at the gaging sites (Table 38), nitrogen appears to be limiting in the lower Portneuf River near the Tyhee site.

In addition to problems of beneficial use support within a subbasin, the effect of nutrients on downstream subbasins is a further concern (e.g., mid-Snake River near Twin Falls). The control of both nitrogen and phosphorus is necessary for protection of beneficial uses not only in the Portneuf River subbasin but in areas downstream such as American Falls Reservoir (Perry et al. 1977). Campbell et al. (1992) remarked that nutrient input in the lower Portneuf River has resulted in "... marked eutrophication in slow moving parts of the [Portneuf] river and American Falls River [sic] downstream."

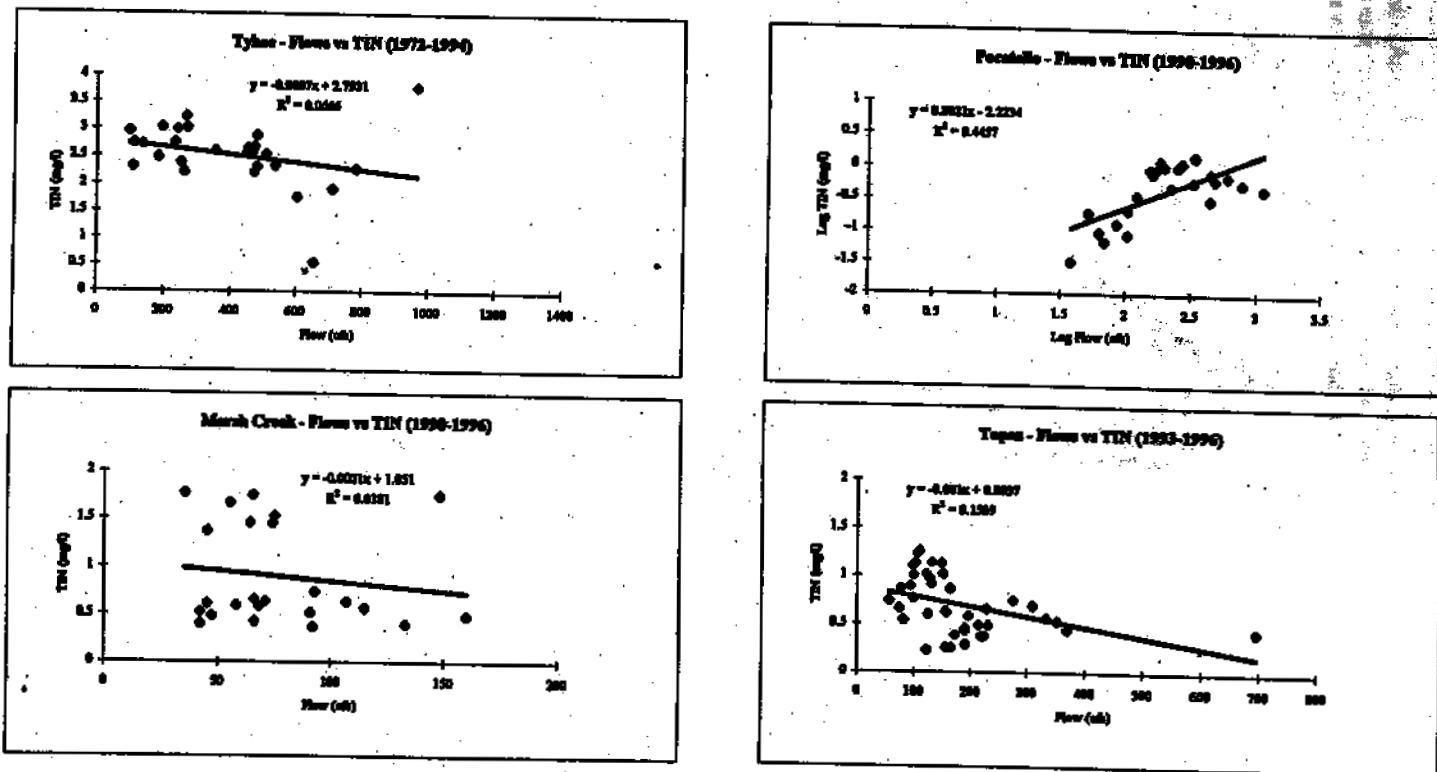

Loads were calculated for total inorganic nitrogen and total phosphorus. TIN was not measured directly but derived by summing nitrate, nitrite (when measured), and ammonia. TIN was chosen for two reasons: 1) it best represents the nitrogen available for uptake by algae and aquatic vegetation and, 2) it includes nitrogen in the form of ammonia which becomes important in the lower Portneuf River. For phosphorus, total phosphorus was used as it was consistently measured by the USGS (Appendix E). For the upper three surface-water stations, only data since 1988 were used, because of decline, sometimes significantly, in nutrient levels between the two periods (Tables 38, 39). At the Tyhee gage site, however, data from both the early and late periods were used. This decision was based on a significant increase in nitrate levels between the two periods and no significant decrease in phosphorus (Tables 38, 39). Furthermore, Campbell et al. (1992) reported an overall increase in ortho phosphate from 1972 to 1991.

Two methods were used to estimate present loads (Appendix G). Loads were calculated by using flow:nutrient regression equations (Figures 15, 16; Appendix F) at the four surface-water stations and by multiplying average nutrient concentration (Table 38) by average daily flow per

Table S7. Estimated nutrient loads in the Portneuf River subbasin.

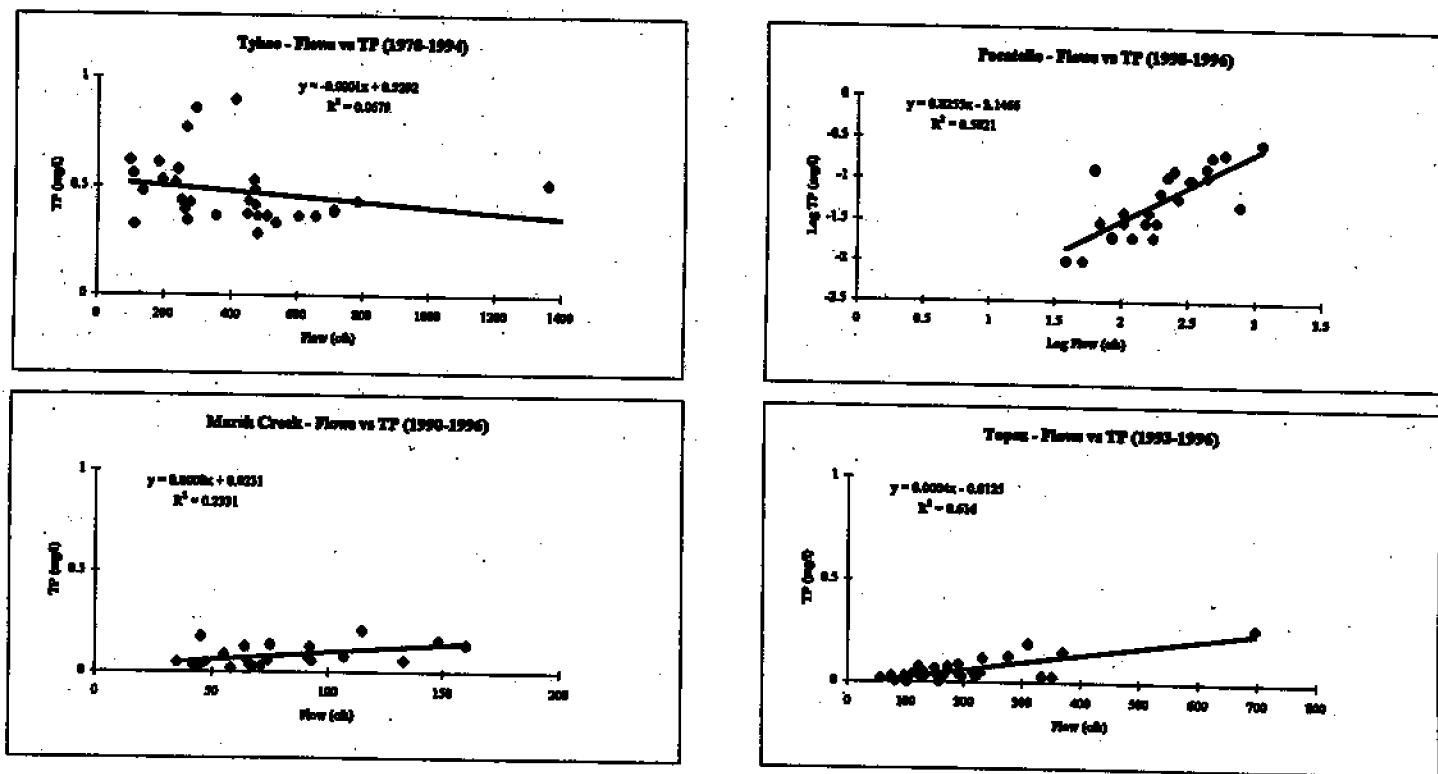

Figure 16. Regression between flow and total phosphorus (TP) at USGS surface-water stations.

month (Appendix G). Secondly, load capacities based on target concentrations were calculated by multiplying the target concentrations of 0.3 mg/l for TIN and 0.075 mg/l total phosphorus by the average daily flow per month (Appendix G).

The estimated loads between the two methods were generally similar (Table 58). Estimated load values based on flow:nutrient regressions (Appendix G) were used except where the relationships were not significant at the 95% confidence level (i.e., TIN and total phosphorus at Tyhee and TIN at Marsh Creek). Values used for the estimated annual load represented at least the 60th percentile for the range of annual loads over the time period except for TIN at the Topaz gage site (Table 59). Michaud South Main Canal diverts water from the Portneuf River above the Tyhee gage site. Estimated loss of nutrients from the river to the canal (Appendix G) were added to the estimated loads at the Tyhee gage.

Hawkins Reservoir

Hawkins Reservoir is listed for both dissolved oxygen and nutrients (Table 19). As previously discussed, no load analysis was done for dissolved oxygen. It is assumed that control of nutrients into the reservoir should reduce aquatic vegetative growth which in turn would decrease opportunities for dissolved oxygen to fall below the state standards.

Water quality information from Hawkins Reservoir is minimal. The only data compiled, other than temperature or dissolved oxygen measurements, was from DEQ monitoring of the reservoir in August of 1997. At that time DEQ sampled for total phosphorus, chlorophyll *a* (a measure of algal density), and water clarity (as measured by a Secchi disk).

Based on the data collected by DEQ, Hawkins Reservoir has characteristics of both eutrophic and non-eutrophic waters. Carlson (1977) developed three indexes for determining the trophic (i.e., eutrophic to oligotrophic) state of lakes and reservoirs. He indexed trophic state of a body of water to water clarity (based on Secchi disk monitoring), chlorophyll *a*, and total phosphorus using the following formulas

$$TSI (\text{Secchi Disk}) = 10^{(6 - (\ln SD / \ln 2))}$$

$$TSI (\text{Chlorophyll } a) = 10^{(6 - ((2.04 - (0.68 * \ln Chl)) / \ln 2))}$$

$$TSI (\text{Total phosphorus}) = 10^{(6 - (\ln (48 / TP) / \ln 2))}$$

where TSI = trophic state index, ln = natural logarithm, SD = Secchi disk depth in m, Chl = chlorophyll *a* concentration in mg/m³, and TP = total phosphorus in mg/m³. The level of chlorophyll *a* (2.1 mg/m³) and the water clarity (Secchi disk reading = 5.5 m) result in TSIs of 38 and 35, respectively, indicating Hawkins Reservoir is mesotrophic (having a medium amount of nutrients and biotic productivity). The total phosphorus concentration (130 mg/m³), however, resulted in a TSI of 74 which would put Hawkins Reservoir in the eutrophic category.

Table 58. Nutrient loads at USGS surface-water stations estimated from flowmetric regression analysis for daily flows and mean concentration (from data after 1989) and average monthly flows, 1955-1995.

Gage site	Total inorganic nitrogen (tons/yr)				Total phosphorus (tons/yr)

Load Analysis

Site-specific targets for nitrogen and phosphorus in the Portneuf River were not attempted. No information was reviewed on site-specific levels for either nutrient necessary to support beneficial uses. In addition, loading, or assimilative, capacity was not estimated also due to lack of data. For the purposes of the loading analysis, the assimilative capacity was considered to be equal to the target load.

The nitrogen target was set for total inorganic nitrogen because it represents the nitrogen most readily available for algae and plant uptake. As total inorganic nitrogen includes nitrate plus nitrite and ammonia, the target accounts for those forms of nitrogen most often measured. Total inorganic nitrogen facilitates comparison of loads from various contributors. For example, in the upper Portneuf River, nitrates tend to be higher than ammonia whereas at the sewage treatment plant, the opposite is true. The 0.3 mg/l threshold for TIN is much less than the State of Utah's indicator of 4.0 mg/l for nitrates (Jim Christensen, Utah Division of Water Quality, personal communication). The TIN target was based on work by Sawyer (1947) who reported 0.3 mg/l of inorganic nitrogen as the threshold value for nuisance aquatic plant growth problems in lakes around Madison, Wisconsin. Imhoff (1955) cited Muller (1953) who stated that excessive plant growth in streams and lakes does not occur if total nitrate nitrogen is below 0.3 mg/l, or total nitrogen is below 0.6 mg/l.

As a margin of safety, a target of 0.3 mg/l for total inorganic nitrogen, per Sawyer (1947), was chosen over 0.3 mg/l of total nitrate as recommended by Muller (1953). Furthermore, a target of 0.3 mg/l of TIN increases the assurance that levels of available nitrogen to phosphorus stay below 10:1.

Even a level of 0.3 mg/l of total inorganic nitrogen may be too high to control nuisance aquatic growth. Bothwell (1992) reported that in a nitrogen-limited stream, kraft mill effluent with a dissolved inorganic nitrogen concentration of about 0.25 mg/l almost doubled the specific growth rate of algae. In setting any target it must be remembered that the TMDL is a dynamic process, i.e., targets can be changed, either higher or lower, based on monitoring.

The form of phosphorus in the Portneuf River differs substantially based on location. Ortho phosphate, which is dissolved, is readily available for plant uptake. Data indicate (Table 38) that ortho phosphorus represents a much higher percentage of the total phosphorus as measured at the Tyhee gage (87% based on mean concentrations from 1970 to 1994) as contrasted to the upper three gage sites (31% to 47% since 1990).

The targets for phosphorus are based on EPA (1986) "Gold Book" which makes recommendations of thresholds for total phosphorus and total phosphates as phosphorus. EPA recommended that total phosphorus (based on Mackenthun [1973]) not exceed a concentration of 0.1 mg/l for prevention of nuisance aquatic growth in streams or flowing waters not discharging directly to lakes or reservoirs. For prevention of nuisance aquatic growth and control of eutrophication in downstream lakes or reservoirs, total phosphates as phosphorus should not exceed 0.05 mg/l in any stream at the point it enters any lake or reservoir. The State of Utah has

a state indicator of 0.05 mg/l of phosphate (Jim Christensen, Utah Division of Water Quality, personal communication).

Some evidence indicates that these phosphorus recommendations may not be low enough to limit algal production via phosphorus. Bothwell (1989) reported that phosphorus was no longer limiting to the peak areal biomass of periphytic diatom communities in experimental troughs in the South Thompson River, British Columbia, at phosphate concentrations of > 0.03-0.05 mg/l. Diatom peak areal biomass was 70% of the maximum attainable biomass from phosphorus enrichment at only 0.001 mg/l of ortho phosphate. Sonzogni et al. (1982) argued that reducing total phosphorus may have little impact, especially in lotic waters, when the portion of phosphorus reduced is not bioavailable (e.g., land runoff is often high in particulate phosphorus, significant portions of which cannot be immediately utilized in the growth of algae and aquatic macrophytes).

The recommended target of 0.075 mg/l total phosphorus allows for a 25% margin of safety from Mackenthun's (1973) recommendation. This concentration also corresponds with the target set in the mid-Snake River TMDL (Division of Environmental Quality 1997).

Natural levels of nitrogen and phosphorus are unknown. The natural input of nitrogen into the Portneuf River is assumed to be low as, except for precipitation and mineralization of organic nitrogen from detritus, there are no known major sources of naturally occurring nitrate (Rupert 1996). An examination of lower values recorded within the subbasin (Table 60) show concentrations of TIN as low as 0.012 and 0.0255 mg/l in the upper Portneuf River and 0.03 mg/l in the lower Portneuf River. Concentrations of total phosphorus levels were as low as 0.003 mg/l in upper Marsh Creek and 0.005 mg/l in the Portneuf River at Topaz. However, numerous TIN and total phosphorus data, both minimum and mean concentrations, exceeded the recommended target concentrations. The extent to which human activities have contributed to these nutrients levels has not been assessed.

The three upper gaging stations (Pocatello, Marsh Creek, and Topaz) along with the Siphon Road bridge will be effectiveness monitoring sites for total inorganic nitrogen and total phosphorus in the Portneuf River. Siphon Road was chosen because the Tyhee gage has been abandoned and, although the bridge is upstream about a mile, it is downstream of the major springs influencing nutrient loads historically measured at the Tyhee gage. The bridge is also just slightly above the pump which diverts water for the Michaud South Main Canal.

Load reductions for nitrogen and phosphorus were not apportioned in the Portneuf River subbasin above Pocatello. Although nutrient information since the late 1980s is minimal, as mentioned previously, agriculture practices (e.g., confining livestock close to the stream, loss of fertilizers from fields) have been identified as contributing to the nutrient load in the Portneuf River. Based on sediment:nutrient regression relationships (Appendix F), sediment reduction at the upper stations should result in a decrease in nutrients, especially total phosphorus. No data were reviewed that indicate urban areas, other than Pocatello-Chubbuck, are significant contributors of nutrients into the Portneuf River. No NPDES-permitted facility upriver of Pocatello collected information on discharge of nitrogen or phosphorus as reported on their

Discharge Monitoring Reports. Even though the contribution of nutrients by NPDES-permitted discharges above the gages is unknown, such input would be included within the overall target load.

The input of total inorganic nitrogen and total phosphorus on a seasonal basis was considered. Minshall and Andrews (1973) found seasonal variation in both nitrogen as nitrate and phosphorus as phosphate. Values for nitrates were highest in the winter, decreased during spring runoff, and declined progressively through the summer, a time of plant uptake. Phosphate concentrations showed less seasonal variation but did exhibit an increase from September through March with a subsequent decline during the growing season. The extent to which either nitrogen or phosphorus exceeds seasonal load capacity is unknown. The tendency for the uptake of phosphorus as phosphates by sediment allows phosphorus availability throughout the growing season regardless of the time of input. Nitrogen on the other hand tends to remain dissolved and will "flow through" in lotic, or stream, systems. If only the Portneuf River were to be considered, seasonal variation in nutrient concentrations would be applied. However, the Portneuf River flows into American Falls Reservoir. Lentic waters (e.g., lakes and reservoirs) act as sinks for both phosphorus and nitrogen, increasing the availability time for uptake by aquatic vegetation. Thus, nitrogen or phosphorus which entered the stream in February could be bioavailable to aquatic vegetation in the reservoir in July when conditions are conducive to algae or macrophytic growth. Due to concern about American Falls Reservoir, it is listed on the 303(d) list for nutrients, no allowance for seasonal variation in nutrient loading is made.

Nutrient contributing sources were identified for the lower Portneuf River below the Pocatello gage site near Carson Street. In addition to upstream input as measured at the Pocatello gage, three other major sources impact nutrient loading in the lower Portneuf River. These other sources include storm water runoff from Pocatello-Chubbuck urban area, Pocatello Sewage Treatment Plant (PSTP) discharge, and numerous springs that drain into the Portneuf River from Carson Street to Siphon Road. Perry and Clark (1990) grouped the springs according to water chemistry: Swanson Road System, Batisse (also spelled Batiste) Spring System, East Side Springs, and Papoose Springs System. An "other" category has been included in the loading analysis to primarily account for additional springs and groundwater input into the lower Portneuf River (see Appendix G). No data were reviewed on contribution of nutrients from Batisse Springs Hatchery, a NPDES-permitted discharge, as monitoring of nutrient input is not included in the Discharge Monitoring Reports regularly submitted to EPA. The load at Tyhee gage site was based on loads at the Pocatello gage site plus urban storm water runoff, PSTP effluent concentrations, and springs input (Appendix G).

One concern with including the springs is uncertainty of natural nutrient levels. Bechtel Environmental, Inc. (1994) compiled concentrations of various parameters from monitoring of wells and springs in Eastern Michaud Flats, generally west of the lower Portneuf River (Table 61). Examination of the information would indicate that target levels of nutrients may well be less than concentrations from representative groundwater and upgradient wells reported by Bechtel Environmental, Inc. However, it must be remembered that these nutrient levels were observed in groundwater which has already been influenced by human activity (Goldstein 1981, Jacobson

Table 61. Potential sources of concentrations (mg/l) of parameters in springs in the lower Portneuf River reach (from Bechtel Environmental, Inc. 1994).

*ND=non detect

**hydrogeochemical regimes

1982, Perry and Clark 1990, Bechtel Environmental, Inc. 1994) and does not represent natural background levels of nutrients in the groundwater of Eastern Michaud Flats.

The three upper surface-water stations show a need for some reduction in nitrogen and phosphorus loads (Table 62). As a margin of safety, the 60th percentile value of 118 tons/year was used as the estimated load of total inorganic nitrogen at Topaz rather than the average of 114 tons/year. Load reductions at the upper three gaging stations ranged from 50-66% for TIN and 15-39% for total phosphorus.

The greatest source of nutrients in the lower Portneuf River is the springs (Table 63). It is estimated the springs contributes over half the total inorganic nitrogen and total phosphorus. Background, as measured at the Pocatello gage represents about 25% of the load for both nutrients. The PSTP contributes about 20% of the total inorganic nitrogen to the river and 14% of the total phosphorus. Storm water contributed 6% or less of TIN or total phosphorus to the Portneuf River.

Total inorganic nitrogen and total phosphorus load estimates based on source input (source-based; Table 63) were less than loads estimated based on flow and nutrient concentrations measured at the USGS surface-water stations plus Michaud Canal removal (site-based; Table 64). The TIN annual load estimate of 1,172 tons/yr falls within the 95% confidence interval of the load estimate from the mean nutrient concentration (TIN lower limit [1,144-357 tons/yr] plus Michaud Canal removal [119 tons/yr] = 906 tons/yr) whereas the total phosphorus load of 148 tons/yr does not (total phosphorus lower limit [216-67 tons/yr] plus Michaud Canal removal [22 tons/yr] = 171 tons/yr). The difference in total phosphorus estimates may, in part, be a result of sediment-bound phosphorus being released, as phosphate, into the water column (Campbell et al. 1992) or input from unknown sources, but is more likely to be an underestimate of the contribution of nutrients from identified sources.

Values derived from both methods, site- and source-based, were used to calculate annual load reductions in nutrients. As the annual loads estimated at Tyhee were greater than the source-based load estimates, the site-based figures were used to estimate load reductions - a difference of 91 tons/yr of TIN and 90 tons/yr of total phosphorus. To account for these increases in TIN and total phosphorus annual loads, the contribution from the sources, except at the Pocatello gage, were adjusted. The majority of the increases were assigned to the springs, 12.5% for total inorganic nitrogen and 100% for total phosphorus as both flows and concentrations may have been underestimated (Appendix G). The estimated input from storm water was increased 7.5% for TIN and 75% for total phosphorus. The non-local runoff coefficients used in the Simple Model to estimate total annual loads from storm water runoff appeared to underestimate both TIN and phosphorus concentrations based on the limited data available (Division of Environment 1980). Increases of 7.5% and 100% for TIN and total phosphorus, respectively, for the FMC IWW ditch were based on the documentation of a high nutrient concentration event at the discharge (Appendix G). Both storm water and FMC IWW ditch input represent less than 2% of TIN loading and 7% of total phosphorus loading. The annual loads at the PSTP were increased only 2.5%, respectively, as the amount of data on flow and nutrient concentration was greater than for any other source. The nutrient loads at the Pocatello gage site were not adjusted for two

Table 62. Estimated reduction in loads (tons/yr) for nutrients at the Pocatello, Marsh Creek, and Topaz USGS surface-water stations.

Site	Present estimated load*	Target load**	Load reduction***	Percent reduction
Total inorganic nitrogen				
Pocatello	259	88	172	66%
Marsh Creek	76	26	51	66%
Topaz^	118	59	60	50%
Total phosphorus				
Pocatello	36	22	14	39%
Marsh Creek	10	6	3	33%
Topaz	17	15	3	15%

*from Table 58 except TIN at Topaz

**average annual load from 1955 to 1995. Annual load derived from the sum of the monthly loads calculated by multiplying the appropriate target concentration by the average flow per month by the number of days per month.

***difference between present and target loads

^apresent estimated load represents the 60th percentile of the range of estimated annual loads

Table 63. Estimated annual loads (tons/yr) from sources that contribute to nutrient loads at the Tybee USGS surface-water station.

Site	Present estimated load*	Percent of present estimated load
Total inorganic nitrogen		
Stormwater - Pocatello-Chubbuck	11	1.0%
Pocatello gage**	259	22.1%
Springs	672	57.4%
FMC IWW ditch	5	0.4%
Pocatello Sewage Treatment Plant	225	19.2%
Total	1172	
Total phosphorus		
Stormwater - Pocatello-Chubbuck	8	5.4%
Pocatello gage**	36	24.4%
Springs	82	55.5%
FMC IWW ditch	2	1.2%
Pocatello Sewage Treatment Plant	20	13.5%
Total	148	

*present estimated loads, except for Pocatello gage, derived by multiplying the mean observed concentration by the average flow projected to an annual load; see Appendix G

**see Table 58

Table 64. Estimated reduction in loads (tons/yr) from sources that contribute to nutrient loads at the Tyhee USGS surface-water station.

Site	Present estimated load*	Percent of present estimated load	Target waste load**	Target load***	Load reduction****	Percent reduction
Total inorganic nitrogen						
Stormwater - Pocatello-Chubbuck	12.1	1.0%		5.1	7.0	58%
Pocatello gage	259	20.5%		88	172	66%
Springs	756	59.9%		80	677	89%
FMC IWW ditch	4.9	0.4%	1.1		3.8	78%
Pocatello Sewage Treatment Plant	230	18.7%	3		227	99%
Total (as estimated at Tyhee gage)*	1263				1086	
Total phosphorus						
Stormwater - Pocatello-Chubbuck	14.0	5.9%		1.3	12.7	91%
Pocatello gage	36	15.1%		22	14	39%
Springs	164	68.9%		20	144	88%
FMC IWW ditch	3.5	1.5%	0.3		3.2	92%
Pocatello Sewage Treatment Plant	20.5	8.6%	0.7		19.8	96%
Total (as estimated at Tyhee gage)**	238				194	

*from Table 63 plus additional load (168 tons/yr of total inorganic nitrogen and 92 tons/yr of total phosphorus) to account for differences between estimated annual load calculated at Tyhee and the source-based estimate of annual loads

**target waste loads and loads derived by multiplying the appropriate target concentration by the average flow projected to an annual load

****difference between present and target loads

†present estimated load at Tyhee of 1144.0 ton/yr (from Table 58) + 119.3 tons/yr lost via Michael South Main Canal

**present estimated load at Tyhee of 215.7 tons/yr + 22.5 tons/yr lost via Michael South Main Canal

reasons: 1) the average annual load represented the 67th and 68th percentiles for the range of estimated annual loads from 1955-1995 of TIN and total phosphorus, respectively, and 2) the percentage of total phosphorus as ortho phosphate is much greater as measured at Tyhee compared to Pocatello gage site indicating sources higher in ortho phosphate. For target load capacities source-based estimates were used because data were available to apportion nutrient load by source.

Based on a target concentration of 0.3 and 0.075 mg/l, respectively, total load reduction for TIN is 1086 tons/yr and for total phosphorus is 194 tons/yr (Table 64). The TIN load reduction represents 86% of the estimated present load. The load reduction for total phosphorus is 82% of the estimated present load. The springs account for the greatest reduction in load. The highest percentage reduction in load is at the Pocatello Sewage Treatment Plant for both TIN and total phosphorus.

As both nutrient and flow information is limited on the listed tributaries (Table 19), no load reductions were estimated. However, the targets (0.3 mg/l of TIN, 0.075 mg/l of TP) will remain the same as at the gaging stations.

Margin of Safety

As mentioned earlier, margins of safety are recommended for both nitrogen and phosphorus targets. The nitrogen target of 0.3 mg/l for total inorganic nitrogen, per Sawyer (1947), allows for less nitrogen than a target of 0.3 mg/l of total nitrate as recommended by Muller (1953), because TIN also includes other forms of nitrogen (e.g., nitrite and ammonia). The target of 0.075 mg/l total phosphorus is a 25% reduction from a recommended 0.1 mg/l for prevention of nuisance aquatic growth in streams or flowing waters not discharging directly to lakes or reservoirs (Mackenthun 1973).

An additional margin of safety was provided based on the estimated annual load used in the nutrient analyses. All load estimates except TIN at Topaz were in the upper 40% (60th percentile or greater) of all annual load estimates (Table 59). The average annual load of TIN at Topaz was estimated at 114 tons/year from 1955 to 1995. To allow for a margin of safety, 118 tons/year which represented the 60th percentile value for that time period was used. Use of the higher estimated annual load from the Tyhee gage site rather than the annual load based estimated input by source also imparts a margin of safety into the load reduction estimates.

Data Gaps

The need for additional data cannot be overemphasized. Information which will help to improve the TMDL in future years includes, but is not limited to, nutrient load from tributaries (e.g., Pocatello Creek), natural background nutrient levels of springs and tributaries, additional nutrient concentration and flow information from the springs, and contribution from other sources (e.g., NPDES-permitted discharges other than FMC and the City of Pocatello) in the lower Portneuf River reach.

Hawkins Reservoir

A target of 0.025 mg/l of total phosphorus in Hawkins Reservoir is recommended. This target is based on the EPA "Gold Book" (1986) which recommends that total phosphates as phosphorus in lakes or reservoirs not exceed 0.025 mg/l to prevent the development of biological nuisances and to control accelerated or cultural eutrophication. No target for nitrogen is proposed. It must be remembered that total inorganic nitrogen and total phosphorus targets are recommended for Hawkins Creek above the reservoir. Reductions in TIN and total phosphorus in Hawkins Creek should decrease the amount of aquatic vegetation in the reservoir.

No load analyses for nutrients were done for Hawkins Reservoir. Part of the reluctance to analyze nutrient loads is due to a lack of data. For example, only a single sampling event for nutrients in August of 1997 (DEQ, unpublished data) is known. No data on nutrient or chlorophyll levels from winter monitoring were located. No nutrient information on Hawkins Creek above the reservoir is known to exist. As a loading analysis was not performed, no margin of safety is suggested.

Data Gaps

More data on Hawkins Reservoir are needed. The discrepancies between the Trophic State Indices, calculated from only one sampling event, do not allow for an accurate characterization of the reservoir. Additional information is essential before attempting a load analysis of nutrients in Hawkins Reservoir. Nutrient sampling in the reservoir and creek throughout the year is needed. Most of Hawkins Creek watershed above the reservoir is dryland agriculture or rangeland and the contribution of nutrients from these land uses along with input from natural sources are unknown.

ACRONYMS AND AN ABBREVIATED GLOSSARY

303(d) list - section 303(d) of the Clean Water Act requires states submit to the Environmental Protection Agency every two years a list of streams within the state that are water quality limited.

ab - above

ac - acre

ACP - Agricultural Conservation Program

ag - agriculture

aka - also known as

Algae - generally, simple aquatic plants, small to microscopic in size, which may be attached to the stream bottom (e.g., filamentous) or found floating in the water column (e.g., phytoplankton).

Anthropogenic - human caused.

avg - average

AWS - agricultural water supply

Bedload - material, including sediment, which moves along or in close proximity to the streambed.

BEI - Bechtel Environmental, Inc.

bel - below

Bio accumulate - when the concentration of a substance (e.g., organic compound, metal) increases in organisms at increasingly higher levels of the food chain.

Bioavailable - when a substance (e.g., organic compound, metal) is available for uptake by an organism.

Biota - the plants, animals, etc., of a system.

BLM - Bureau of Land Management

BMP - best management practice

BURP - Beneficial Use Reconnaissance Project

*C - degrees centigrade. The following formula can be used to convert centigrade (C) to
degrees Fahrenheit (F): $(Cx9/5)+32=F$.

cfs - cubic feet per second

Char - a member of the salmon family closely related to the trouts. Lake trout, brook trout, bull trout, dolly Varden are examples of char.

Chl - chlorophyll a

CRP - Conservation Reserve Program

CWB - cold water biota

Depth fines - amount of sediment by volume in the upper layer (usually < 24 inches) of the streambed.

DEQ - Division of Environmental Quality

Drift - organisms moving in the water column with the current.

DWS - domestic water supply

Embeddedness - the extent to which streambed cobble or rocks are surrounded by sediment. A low level of embeddedness results in greater interstitial space conducive to the production of macroinvertebrates preferred as food by salmonid and other fish species.

EPA - U. S. Environmental Protection Agency

Erosion rate - soil which is lost from an area via wind or precipitation, for example, top soil lost from an agricultural field following a summer rainstorm. Soil lost may or may not be deposited in a body of water.

Eutrophic - a term referring to waterbodies which are characterized by high levels of nutrients and high biotic productivity.

*F - degrees Fahrenheit. The following formula can be used to convert Fahrenheit (F) to centigrade (C): $(F-32)x5/9=C$.

FSA - Food Security Act

ft - feet

Geometric mean - a mean calculated by finding the n th root of the product of multiplying the measurements in n samples. For example, the measurements of 3 samples were 8, 5, and 11. The product of those measurements is $8 \times 5 \times 11 = 440$. The cube root of 440 is $\sqrt[3]{440} = 7.6$. Therefore the geometric mean of 8, 5, and 11 is 7.6.

Hydrograph - how the flow of a stream changes over the year. The hydrograph of a typical undammed Idaho stream is high flows in the spring time associated with snow melt followed by decreasingly lower flows through the early fall after which flows will increase due to increased precipitation.

IDAPA - Idaho Administrative Procedure Act

IDFG - Idaho Department of Fish and Game

Intergravel dissolved oxygen - dissolved oxygen in water flowing through the upper layers of the streambed. Intergravel dissolved oxygen is essential for the survival of salmonid eggs buried in the subsurface gravels.

IWW - industrial waste water

l - liter

Lentic - non-flowing water (e.g., lakes and reservoirs).

LHS - Lava Hot Springs

ln - natural logarithm

Load - total amount of a pollutant usually in reference to the amount which reaches a waterbody.

Load allocation - amount of pollutant usually expressed as a mass per unit time (e.g., tons/day) allocated to a non-point source which, if not exceeded, should result in the support of beneficial uses within a waterbody.

Loading - total amount of a pollutant entering a waterbody usually expressed in mass per unit time (e.g., tons/day). Loading is calculated by multiplying the concentration by flow.

Lotic - flowing water (e.g., streams).

m - meter

m^2 - square meter

m^3 - cubic meter

Macroinvertebrates - small animals (e.g., insects, snails, worms) which inhabit the surface and below surface areas in a stream.

Macrophyte - rooted and floating aquatic vegetation.

Margin of safety - an amount by which a load is reduced to account for any uncertainty often caused by a lack of data.

max - maximum

Mesotrophic - a term referring to waterbodies which are characterized by levels of nutrients and biotic productivity somewhere between eutrophic and oligotrophic.

mg - milligram

mg/l - milligrams per liter, also is equivalent to parts per million

mi² - square miles

min - minimum

ml - milliliter

msl - mean sea level

ND - no discharge; non detect

nda - no date available

NPDES - National Pollution Discharge Elimination System

NRCS - Natural Resources Conservation Service

NTU - nephelometric turbidity units - a measure of turbidity in the water.

NWS - National Weather Service

Oligotrophic - a term referring to waterbodies which are characterized by low levels of nutrients and low biotic productivity; oligotrophic lakes are sometime referred to as "sterile" lakes

Organic compound - carbon-based compounds which can be natural (e.g., fecal material) or human made (e.g., polychlorinated biphenyl) in origin.

Organochlorine compound - organic compounds which include chlorine most of which are human made (e.g., polychlorinated biphenyl).

PCB - polychlorinated biphenyl

PCR - primary contact recreation

Periphyton - organisms, e.g., microscopic plants and animals, which are attached to submerged objects such as plant stems, rocks, etc.

Phytoplankton - tiny floating plants (e.g., algae, diatoms).

Poky - Pocatello

ppm - parts per million

Primary Contact Recreation - water-related activities (e.g., swimming) where ingestion of water may be common.

PSTP - Pocatello Sewage Treatment Plant

R - river

R² - correlation index; a measurement of the relationship between two variables in a correlation analysis. R² ranges from 0 to 1 with the values closest to 1 indicating the strongest relationship.

Regression - the comparison of two parameters to determine if a relationship exists. For example, a positive relationship exists between an individual's height and the length of their leg.

Riparian - that area next to a stream that is heavily influenced by the stream through the availability of water. Examples of vegetation associated with riparian areas include sedges, rushes, and willows.

Salmonids - those members of the salmon family of fishes including trout, char, salmon, whitefish.

SAWQP - State Agricultural Water Quality Program

SCR - secondary contact recreation

SD - Secchi disk - around black and white disk used to measure the clarity of water.

SD - standard deviation

SE - standard error

Secondary Contact Recreation - water-related activities (e.g., fishing) where ingestion of water is unlikely.

Sediment delivery rate - rate (percentage) of erosion that is deposited in a body of water.

Sediment load - mass per unit time (e.g., tons/year) of sediment within a waterbody.

Sediment yield - rate of sediment lost from an area of land or length of stream that is deposited in a water body expressed in mass per area or length per time (e.g., tons/acre/year, tons/mile/year).

Sinuosity - the curving back and forth of a stream (i.e., deviation from a straight line).

spp. - species

SS - suspended sediment; salmonid spawning

Standards - an amount of pollutant beyond which a waterbody will not support its beneficial use. A standard is found in official state and federal rules or regulations.

STP - sewage treatment plant

Suspended sediment - sediment which is suspended in the water column.

Target - an amount of pollutant beyond which a waterbody will not support its beneficial use. A target is not included in official state rules or regulations. Targets are often associated with narrative state water quality standards and reflect the most current scientific understanding.

TIN - total inorganic nitrogen - the inorganic component of nitrogen in a system which is most readily available for uptake by plants or algae; includes nitrate + nitrite + ammonia.

TMDL - total maximum daily load - maximum amount of pollutant which can be inputted on a daily basis into a waterbody without affecting beneficial use of the waterbody.

TP - total phosphorus

TSI - trophic state index - a method to classify the trophic (generally - the amount of nutrients) state of lakes developed by Carlson (1977).

TSS - total suspended solids. Total suspended solids include an organic component not found in measurements of suspended sediment.

Turbidity - the ability of water to pass light. Higher turbidities result in less light passing into the water.

$\mu\text{g/l}$ - micrograms per liter, $1000 \mu\text{g/l} = 1 \text{ mg/l}$, also is equivalent to parts per billion

um - microns (micrometers), 1000 microns = 1 mm

USGS - U. S. Geological Survey

Waste load allocation - amount of pollutant usually expressed as a mass per unit time (e.g., tons/day) allocated to a point source (e.g., an NPDES-permitted discharge) which, if not exceeded, should result in the support of beneficial uses within a waterbody.

Waterbody - stream, lake, or reservoir.

yr - year

Appendix A

State of Idaho water quality standards

Table A-1. State of Idaho water quality numeric standards (from Idaho Department of Health and Welfare Water Quality Standards and Wastewater Treatment Requirements). Max = maximum, avg = average, and min = minimum.

Beneficial use	pH	Dissolved gas ^a	Criteria			Ammonia	Interpreted dissolved oxygen	Radioactivity
			Chlorine ^b	Toxic substances ^c				
Cold Water Biota	≥ 6.5 and < 9.5	$\leq 110\%$ saturation	19.0 mg/l, 1-hr avg 11.0 mg/l, 4-day avg	\leq CMC or CCC \leq Human Health criteria ^{d,e}		varies ^f		
Warm Water Biota	≥ 6.5 and < 9.5	$\leq 110\%$ saturation	19.0 mg/l, 1-hr avg 11.0 mg/l, 4-day avg	\leq CMC or CCC \leq Human Health criteria ^{d,e}		varies ^f		
Salmonid Spawning	≥ 6.5 and < 9.5	$\leq 110\%$ saturation	19.0 mg/l, 1-hr avg 11.0 mg/l, 4-day avg	\leq CMC or CCC \leq Human Health criteria ^{d,e}		varies ^f	≥ 5.0 mg/l, 1-day min ≥ 6.0 mg/l, 7-day avg max	
Primary & Secondary Contact Recreation Domestic Water Supply								varies ^f

^aat atmospheric pressure at point of collection.

^btotal residual chlorine

^ccriteria from 40 CFR 131.36(b)(1) as modified by Section 258.07 of the Water Quality Standards and Wastewater Treatment Requirements; CMC (Criteria Maximum Concentration) - maximum concentration for one hour; CCC (Criteria Continuous Concentration) - maximum concentration for five days

^dvaries according to temperature and pH

^efor consumption of organisms only

^ffor consumption of water and organisms

-varies based on results; criteria from Idaho Department of Health and Welfare (rule) Idaho Rules for Public Drinking Water Systems based on 40 CFR 141.13 and 16

Appendix B

Results of Beneficial Use Reconnaissance Project Monitoring

Table B-1. Status of waterbodies in the Northwest River subwatersheds as to support of their beneficial uses (information from Beneficial Use Restorability Project monitoring).

Annual average 11,361

Table E-1. Mean values for surface water parameters measured at 16 sites in the
Portneuf River in the Pocatello area in July and October, 1992 and February and April,
1993 (from Bechtel Environmental 1996).

Value	Total suspended solids (mg/l)	Ammonia NH3 as N (mg/l)	Nitrate NO3 as N (mg/l)	Ortho-phosphate PO4 as P (mg/l)	Total phosphorus (mg/l)
Mean*	14.5	0.5	1.2	0.26	0.34
Number of sites	14	16***	16	16	16
Range**	4.0-52.0	0.3-3.4	0.42-2.26	0.03-0.97	0.06-1.05

*average of all values for all sampling periods and all sampling sites

**range of mean values by sampling site

***ammonia not detected at 10 sites which were assumed to be 0 mg/l for averaging

Methods to estimate nutrient loads

Methods to Estimate Nutrient Loads at USGS Surface-water Stations

Estimated Present Load Based on USGS Data

Present loads were estimated at each surface-water station using information (i.e., flow and nutrient concentrations) collected by the U. S. Geological Survey. Some of the information from the Tyhee site includes information gathered at Siphon Road from September 1972 to March 1975 (5 dates). Siphon Road is upstream of Tyhee about one river mile. As mentioned in the main text, daily flow information was used to estimate nutrient concentration from the regression equation (the regression method). For example, flow for 1 November 1955 at the Topaz surface-water station was 110 cfs. Putting this value into the flow:total phosphorus (TP) regression equation (Appendix F),

$$\text{TP Concentration} = 0.000367(110) - 0.01252,$$

yields a total phosphorus concentration in mg/l of 0.028. To convert mg/l into tons/day, the concentration is multiplied by the flow and by 0.0027 (a conversion factor),

$$\text{Tons/day of TP} = (\text{TP mg/l}) \times (\text{Flow cfs}) \times 0.0027,$$

or 0.008 tons/day. Each daily load was then summed to yield the annual load (total inorganic nitrogen - Tables G-1, G-2, G-3, G-4; total phosphorus - Tables G-5, G-6, G-7, G-8). The average annual load was estimated from annual loads from 1955 to 1995.

Each flow:nutrient regression equation was tested for significance to determine if flow could actually explain any of the variance in nutrient concentrations. The 95% confidence limit was used to determine significance.

For comparison purposes, loads were also calculated based on average monthly load and mean nutrient concentration (the mean method). To continue with the Topaz example, the average flow for November 1955 was 126 cfs. The mean concentration for total phosphorus based on 40 samples collected at the Topaz gage from 1993 to 1996 was 0.054 mg/l (Table 38). The numbers are then put into the following equation:

$$\text{Tons/day of TP} = (\text{Mean Concentration}) \times (\text{Mean Monthly Flow}) \times 30 \text{ days/month} \times 0.0027.$$

Based on this method, there was a total phosphorus load for November 1955 of 0.55 tons/yr versus 0.34 tons/yr using the regression method. Each monthly load was then summed to yield the annual load (total inorganic nitrogen - Tables G-9, G-10, G-11, G-12; total phosphorus - Tables G-13, G-14, G-15, G-16). The average annual load was estimated from annual loads from 1955 to 1995.

Targets

The mean method was used to calculate target loads. The target concentration (0.3 mg/l total inorganic nitrogen and 0.075 total phosphorus) was substituted for the mean concentration (total inorganic nitrogen - Tables G-17, G-18, G-19, G-20; total phosphorus - Table G-21, G-22, G-23, G-24).

Confidence limits

Confidence limits were calculated for the average annual loads estimated by both methods for both nutrients (Table 58). A 95% confidence level was used.

Estimated Loads from Nutrient Sources in the Lower Portneuf River

Several possible sources of nutrients contributing to nutrient loads as measured at the Tyhee surface-water station were identified. The first source, which can also be looked at as a background source, is the load at the Pocatello gage site. The methods used to estimate nutrient loads at the gage were discussed above.

Stormwater

Information on land use from the cities of Pocatello and Chubbuck was used in a model to estimate pollutant inputs into the Portneuf River from stormwater runoff. Land use designations and attendant areas were taken from Surface and Wessel (1995). The model generates pollutant loads from area of land use, precipitation (estimated to be 12 inches for the urban area) and several factors which are based on the type of land use, i.e., percent impervious surface area, runoff coefficient, and the fraction of average annual precipitation available as runoff. As no local land use dependent factors were available, factors from other cities with similar circumstances to Pocatello were used. Todd Maguire, Idaho Division of Environmental Quality, set up and ran the model for the TMDL. The results are presented in Table G-25.

It should be noted that some nutrient input from the city of Pocatello has the potential to be counted twice - once in the model as stormwater runoff and then again at the Pocatello gage. Such a scenario would occur if monitoring at the gages was done at a time of stormwater runoff (e.g., spring snowmelt or warmer weather thunderstorms). However, this double counting was felt to have a minimal effect on the numbers generated and was ignored.

Pocatello Sewage Treatment Plant Effluent

The Pocatello Sewage Treatment Plant (PSTP) routinely monitors their effluent output and accompanying nutrient constituents as part of their NPDES permit requirements. Information on total and mean monthly effluent flow and mean monthly nutrient concentrations since 1986 was provided by PSTP personnel (Brent Hokanson and Candy Ross). Only ammonia and ortho phosphate levels were consistently monitored. During some years ortho phosphate was sampled

while in other years total ortho phosphate was measured, all ortho phosphate numbers were lumped together for the load estimate.

Based on ammonia and total ortho phosphate data, total inorganic nitrogen and total phosphorus loads from the PSTP were estimated. From December to May, total inorganic nitrogen was considered equal to the ammonia concentration in the effluent. However, in the warmer months (June through November), the PSTP often manipulates the form of nitrogen in their discharge effluent through nitrification (conversion of ammonia to nitrate or nitrite). Consequently, any measurement of ammonia in that time period would underestimate the total inorganic nitrogen load ($TIN = \text{ammonia} + \text{nitrate} + \text{nitrite}$). To account for TIN in the warmer months, an average concentration of ammonia estimated from those months (December through May) when nitrification does not occur was used in the total load calculation. Eric Stewart (Idaho Division of Environmental Quality/Pocatello, personal communication) sampled PSTP effluent on 24, 25 June 1998. The 24-hour sampling indicated that ortho phosphate (0.327 mg/l as phosphorus) represented 79.9% of the total phosphorus (1.30 mg/l as phosphorus) measured.

From information provided by the city, mean daily flow per month and mean daily concentrations of ammonia and ortho phosphate were averaged by month from January 1986 to July 1998. The average mean daily flow per month (1986-1998) was multiplied by the average mean daily concentration (1986-1998), the days per month, and 0.0027 to produce the monthly load. Sum of the monthly loads was the estimated load to the Portneuf River from the PSTP. To convert load from ortho phosphate to total phosphorus, the estimated load was divided by 0.799 based on Stewart's results (Table G-26).

Springs

Numerous springs are found along the lower Portneuf River from Pocatello downstream. Information was not available from each spring. However, various authors have grouped the springs into systems based on water chemistry (Goldstein 1981; Perry and Clark 1990). For this evaluation, Perry and Clark's grouping of four systems was used. The systems generally going from upstream to downstream were: Swanson Road System, Batise Spring System, East Side Springs, and Papoose Springs System. By lumping springs into groups, data on individual springs were not needed when values for the groups were available.

To project load, flow and nutrient concentrations were required. For some springs, average flow was based on only three measurements, e.g., Swanson Road, East Side, and Papoose springs groups (Table G-27). Batise Springs had the largest number of measurements with flow ranging from 5.73 to 60 cfs. All measurements except a 7.2 cfs observation questioned by Balmer and Noble (1979) were used to get average flow of 28.9 cfs at Batise Springs (Table G-28). Of nine measurements used to estimate flow from Batise Springs, only a three measurement-average of 5.73 cfs were less than 20 cfs. If, for example, these values were not indicative of typical flows emanating from Batise Springs, then the average without these lower flows would increase to 38.8 cfs. Such an increase of almost 10 cfs would substantially raise the estimated input of nutrients from the Springs to the Portneuf River. To estimate flow out of Batise Springs group, 2.08 cfs (the difference in flow as measured by Perry and Clark [1990]

between Batise Springs and the Batise Spring group) was added to the average flow out of Batise Springs.

Flows in the lower Portneuf River are influenced not only by springs but also by groundwater (Jacobson 1982, Bechtel Environmental, Inc. 1994). Brock (1989) estimated additional flow input into this river reach at 143.5 cfs from the Pocatello USGS gage site near Carson Street to Rowlands and 128.3 cfs from the PSTP effluent to Siphon Road. Although, these estimates were made at low flows (September 1982 and June to August 1989) during a time period of low precipitation, Brock's numbers were used in the loading analysis. In the loading analysis, 129.7 cfs is contributed to the PSTP effluent to Siphon reach by Batise Spring, East Side, and Papoose Springs groups (Table G-28). Although, the current estimate is almost exactly what Brock estimated, he included Perry's (1981) E4 spring in his calculation, whereas, for the current calculation, the E4 spring was included in the Swanson Road group. Nevertheless, no additional springs or groundwater input was estimated for the reach from the PSTP effluent to Siphon Road. For the upper reach, however, the Swanson Road group input of 17.5 cfs and the estimated flow from the FMC IWW ditch of 3.7 cfs were subtracted from Brock's estimated figure of 143.5 cfs to yield an additional flow input of 122 cfs for the upper reach from Carson Street to Rowlands. It should be noted that this flow of 122 cfs also includes input from Pocatello Creek.

Data compiled on nutrient concentrations are presented in Table G-29. Nutrient concentrations used in the load analysis were based on information gathered by Bechtel Environmental, Inc. (1996). From a visual examination of Table G-29 it would appear that the Bechtel numbers (Table G-30) might underestimate nutrient concentrations in the springs, especially TIN and total phosphorus from Batise Spring group. Nevertheless, Bechtel data were used for three reasons: 1) sampling was done quarterly; 2) data was gathered from all four springs groups; and 3) data was relatively recent (1992-1993). Only data from spring sites that were sampled quarterly and drain into the Portneuf River above the Tyhoe gage site were used. Springs monitored by Bechtel Environmental were assigned to a springs groups based on Perry and Clark (1990). Mean concentrations of springs sites with assigned groups are presented in Table G-30. For lack of better data, nutrient concentrations for the Swanson Road group were used for all springs, groundwater, and Pocatello Creek input from Carson Street to Rowlands. All concentrations that were not detected or below the detectable limit were treated as 0 mg/l.

To complete the load estimate, the mean method, as described previously, was used. The average flow was multiplied by the mean concentration, 0.0027, and 365 days/year. The estimated loads due to springs are found in Table G-31.

FMC IWW Ditch

The FMC IWW ditch is an NPDES-permitted discharge located just above the Interstate 86 bridge. The average discharge since January of 1993 is 3.7 cfs (Kelly Packard, FMC, personal communication). Little information was found on nutrient input by the IWW ditch. For the analysis, concentrations (Table G-31) measured in July of 1993 by Bechtel Environmental, Inc. (1996) were used although these numbers may be low based on the other limited information.

available (Table G-29). Waste load contributions to the Portneuf River by the IWW ditch are 4.53 and 1.74 tons/year for total inorganic nitrogen and total phosphorus, respectively (Table G-31).

Michaud Canal

Just above the Tyhee gage, water is diverted from the Portneuf River into the Michaud South Main Canal from 1 May to 1 October. Average flow from 1978 to 1993 (a time period which more closely aligns with the period of record at the Tyhee gage) was 114 cfs (34,700 acre-feet of water over a 153-day season; Alan Oliver, Bureau of Indian Affairs, personal communication). Concentrations of TIN and total phosphorus observed at the Tyhee gage from the early 1970s to 1994 were used to calculate average annual loads for TIN and total phosphorus for water entering the Michaud South Main Canal (Table 38). Total estimated average annual loads of TIN and total phosphorus leaving the system via the Michaud South Main Canal (i.e., not counted as part of the load at the Tyhee gage) were 119.27 tons/yr and 22.48 tons/yr, respectively.

Targets

Flows and target concentrations were used to calculate target loads. Target loads for the springs, PSTP, and FMC IWW ditch were calculated from average flows multiplied by the target concentration (0.3 mg/l total inorganic nitrogen and 0.075 total phosphorus) and the results converted to annual loads. For stormwater, the target load concentrations were substituted for estimated concentrations to figure the annual load.

Table G-1. Daily total inorganic nitrogen loads based on the regression equation ($TIN = -0.001(\text{flow}) + 2.793$) summed by month, Tyhee USGS surface-water station, 1986-1993.
